5.23.4.4 Sexual Abuse

There has been considerable interest and controversy regarding the role of sexual abuse as a risk factor for the development of eating disorders. Clinical accounts and the observation in some studies of a high incidence of sexual abuse in eating disorder patient samples (Oppenheimer, Howells, Palmer, & Chaloner, 1985) were followed by further clinical reports and numerous empirical studies yielding conflicting findings (Fallon & Wonderlich, 1997). Fallon and Wonderlich summarized the literature and concluded that: (i) childhood sexual abuse appears to be positively associated with bulimia nervosa; (ii) there is less evidence for this association in anorexia nervosa; (iii) childhood sexual abuse does not appear to be a specific risk factor for eating disorders (i.e., it is no higher for eating disorders than in psychiatric controls); (iv) childhood sexual abuse does appear to be associated with greater levels of comorbidity among those with eating disorders, however, there is not strong evidence that it predicts a more severe eating disorder; and (v) a more complex approach to the definition of sexual abuse has led to better prediction of later disturbances in eating. It is indisputable that a significant subgroup of women from some clinical eating disorder samples have a history of sexual abuse and that careful assessment and treatment is important in the process of dealing with resulting feelings of shame, distrust, and anger (Fallon & Wonderlich, 1997).

5.23.5 ETIOLOGY

A complete understanding of anorexia nervosa and bulimia nervosa must account for factors that predispose individuals to each of the eating disorders. Theory should be able to delineate the variety of developmental experiences that interact with these factors to initiate symptom expression as well as account for the maintaining variables (biological, psychological, and interpersonal) and the key variations in the symptom picture. Although current models are unable to specify all of these elements in precise detail, research and clinical observations since the mid-1970s have improved the understanding of eating disorders, which in turn, has led to more sophisticated treatment recommendations.

In the latter half of the twentieth century single-factor causal theories have been replaced by the view that eating disorders are "multidetermined" (Garfinkel & Garner, 1982; Garner, 1993; Garner & Garfinkel, 1980). The symptom patterns represent final common pathways resulting from the interplay of three broad classes of predisposing factors shown in Figure 2. The role of cultural, individual (psychological and biological), and familial causal factors are presumed to combine with each other in different ways leading to the development of eating disorders. The precipitants are less clearly understood except that dieting is invariably an early element. Perhaps the most practical advancements in treatment have come from increased awareness of the perpetuating effects of starvation with its psychological, emotional, and physical consequences (Figure 2).

5.23.5.1 Genetic Contributions

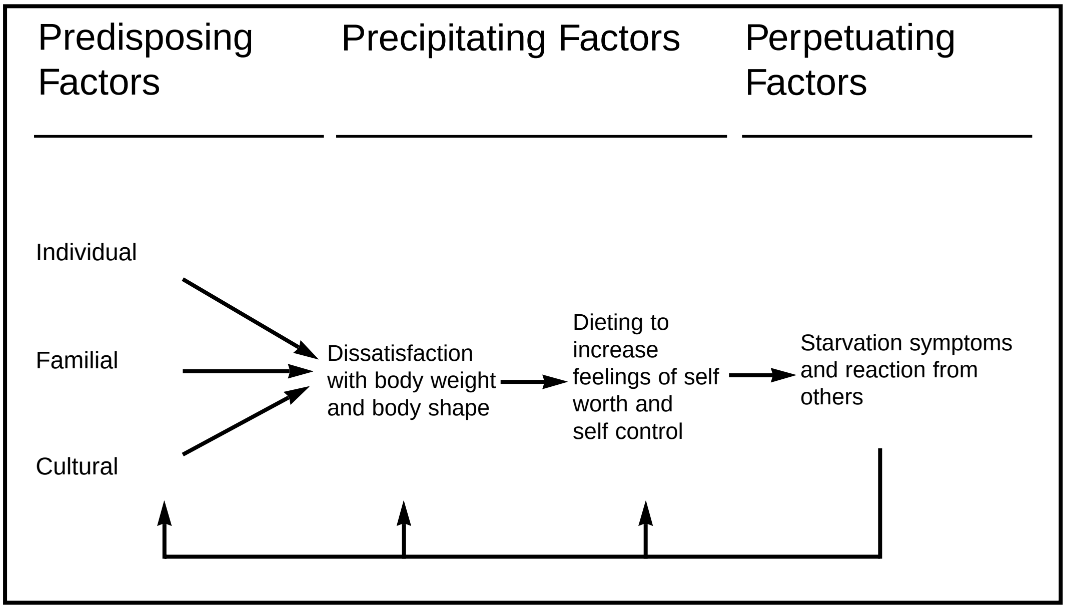
The evidence for genetic vulnerability to anorexia nervosa comes from approximately 100 twin pairs culled from selected twin case report summaries and from twin studies (Garfinkel & Garner, 1982; Holland, Sicotte, & Treasure, 1988). These reports indicate concordance rates of more than 50% for monozygotic twin pairs compared to less than 10% for dizygotic twins. This is in contrast to one study of 11 twin pairs (5 monozygotic) where none of the co-twins was found to be concordant for anorexia nervosa (Waters, Beaumont, Touyz, & Kennedy, 1990). Strober, Lampert, Morrell, Burroughs, and Jacobs (1990) found first degree relatives of eating disorder patients have a greater risk of having anorexia nervosa. Monozygotic twins have a concordance rate of about 50% compared to about 10% for dizygotic twin pairs (Holland et al., 1988). These studies suggest that there may be a genetic component to the transmission of anorexia nervosa; however, it is not at all clear what is inherited. Is it the specific disorder, a particular personality trait associated with the disorder, or a general vulnerability to psychiatric disturbance? Moreover, the concordance data on twins reared together does not conclusively distinguish between genetic and environmental transmission (Holland et al.).

5.23.5.2 Developmental Theory

Defined in broad terms, many theories have offered developmental explanations of eating disorders. Some formulations have emphasized intrapsychic mediation and others have highlighted interactional factors. Together they have provided a rich understanding of a range of psychological themes that may account for both anorexia nervosa and bulimia nervosa.

Many of the early psychodynamic writings on eating disorders emphasized anorexia nervosa as a rejection of adult femininity. This theme was refined and extended by Crisp (1965) who contends that the central psychopathology of both anorexia nervosa and bulimia nervosa is related to fears of the psychological and biological experiences associated with adult weight. According to this view, starvation becomes the mechanism for avoiding psychobiological maturity because it results in a return to prepubertal appearance and hormonal status. This regression is thought to provide relief from adolescent turmoil and conflicts within the family. Moreover, patients report experiencing themselves as younger following extreme weight loss, and this may be due to the reversal of mature adolescent hormonal profiles that form the biological substrata for psychological experience (Crisp, 1980).

Other developmental theorists have attributed eating disorders to various types of parenting failure. Bruch (1973) and Selvini-Palazzoli (1974) provided a developmental paradigm in which the mother superimposes her own inaccurate perceptions of the child's needs on the child. Such invalidation of the child's experiences results in an arrest of cognitive development and is manifest in debilitating feelings of ineffectiveness that are later evident in adolescent struggles for autonomy and control of the body. Bruch (1973) postulated



Predisposing Factors
Precipitating Factors
Perpetuating Factors
Individual
Familial
Cultural
Dissatisfaction with body weight and body shape
Dieting to increase feelings of self worth and self control
Starvation symptoms and reaction from others

Figure 2 Eating disorders as multidetermined disorders. ("Pathogenesis of anorexia nervosa," by D. M. Garner, 1993, *The Lancet, 341,* p. 1632. Copyright 1993 by *The Lancet*. Reprinted with permission.)

that these early parenting failures lead to fundamental deficits in self-awareness, including the way that the body is perceived and experienced.

A similar view is expressed by theorists working from an object relations model to account for eating disorders (Johnson & Connors, 1987; Masterson, 1977; Stern, 1986; Sugarman, Quinlan, & Devenis, 1982). According to this view, normal development is characterized by the process of separation–individuation, a state achieved by consistent interactions with a primary caretaker who is highly responsive to the needs of the child. Success is reflected by the child's progressive internalization of the ability to accurately recognize, respond, and regulate internal needs and impulses without contact with the immediate caregiver. Accordingly, the different personality structures of eating disordered patients reflect developmental arrest at particular phases of the process of separation–individuation. The eating disorder symptoms are an attempt to cope with needs stemming from incomplete self-development or an interruption of the separation–individuation process.

The self-psychology perspective of Kohut (1971) has also been used to account for eating disorders as a reflection of developmental arrest in the separation–individuation process (Casper, 1983; Goodsitt, 1985; Swift & Letven, 1984). According to this conceptual scheme, the eating disordered patient's lack of a cohesive sense of self is the direct result of the primary caregiver's failure to provide essential functions during development. These include mirroring, tension regulation, and integration. The obsessive concern about eating and repeated bouts of bingeing and vomiting serve organizing and tension-regulation functions in the attempt to modulate basic deficits in "self-structures." These symptoms become an organizing event in one's life and provide intense stimulation that numb the anguish and emptiness that pervade the eating disordered patient's experience. There is growing empirical evidence to support the clinical view that intense separation distress is common among eating disorders and that many patients demonstrate marked separation anxiety in response to severely as well as mildly stressful situations (Armstrong & Roth, 1989).

Others have emphasized the motivation for binge eating as an attempt to escape negative aspects of self-awareness (cf. Heatherton & Baumeister, 1991). According to this view, the binge eater experiences negative self-evaluations and concerns about perceived negative evaluations from others that are accompanied by anxiety and depression. Binge eating provides a means of avoiding this unpleasant state of negative self-awareness through the narrowing of attention to one facet of the immediate environment.

Strober (1991) has drawn together developmental theory, psychobiology, and personality genetics in offering a valuable understanding of the adaptive mechanisms behind the range of symptoms seen in eating disorder patients. He integrates modern psychoanalytic concepts of development with constructs indicating that: (i) individual differences may be expected in the internal regulators of arousability or temperament that organize self-experiences, and (ii) heritable personality traits, and their presumed biological substrata, set limits within which behavior patterns are expressed. Strober accounts for the differences in traits seen in subgroups of eating disorder patients by incorporating Cloninger's (1989) concept of three bipolar, and primarily genetically determined, dimensions of personality that appear to account for remarkable consistency over time in both normal and psychopathological behavior.

5.23.5.3 Familial Factors

Some of the earliest descriptions of anorexia nervosa emphasized the role of the family in the development of the disorder (cf. Garfinkel & Garner, 1982). The possible role of the family in the development of anorexia nervosa and bulimia nervosa has been described by writers from a range of theoretical orientations (Bruch, 1973; Dare & Eisler, 1997; Garfinkel & Garner, 1982; Humphrey, 1989; Minuchin, Rosman, & Baker, 1978; Root, Fallon, & Friedrich, 1985; Schwartz, Barrett, & Saba, 1985; Selvini-Palazzoli, 1974; Vandereycken, Kog, & Vanderlinden, 1989). A major advancement in family therapy with eating disorders was the formulation of the structural approach of Minuchin et al. (1978). They identified a number of characteristics of the interactions encountered in eating disordered families, including enmeshment, overprotectiveness, rigidity, and poor conflict resolution. The systemic model was applied to eating disorders by Selvini-Palazzoli (1974) and overlaps considerably with the structural model. The systemic approach holds that the identified patient serves an essential homeostatic or stabilizing role within the family. A second generation of family theorists have integrated and greatly elaborated earlier approaches providing very specific advice regarding the treatment of bulimia nervosa (Root et al., 1985; Schwartz et al., 1985; Vandereycken et al., 1989).

Regardless of their orientation, most individual and family theorists have emphasized that anorexia nervosa often represents a developmental struggle for autonomy, independence, and individuality. These issues are very likely to surface in adolescence, when the vulnerable individual, parents, or entire family are forced to deal with emergent developmental realities. In the only controlled trial examining the efficacy of family therapy for anorexia nervosa, Russell, Szmukler, Dare, and Eisler (1987) found that family therapy was superior to individual therapy for younger patients. This study, as well as clinical experience, suggests that family therapy should be routinely employed as the treatment of choice for young eating disorder patients.

5.23.5.4 The Addiction Model

The term compulsive overeating is somewhat problematical since the *DSM-III-R* diagnostic criteria for OC disorder specifically excludes those who meet an eating disorder diagnosis. Nevertheless, the suggestion that binge eating is compulsive behavior and a form of substance abuse has intuitive appeal on a number of grounds. Studies have shown both that substance abuse and poor impulse regulation are common features in bulimia nervosa (Garner, Rockert, et al., 1985; Garner et al., 1993; Hatsukami, Owen, Pyle, & Mitchell, 1982). Moreover, bulimia nervosa shares several features with addictive disorders that have been summarized by Bemis (1985) as: (i) "loss of control, (ii) preoccupation with the abused substance, (iii) use of the abused substance to cope with stress and negative feelings, (iv) secrecy about the behavior, and maintenance of the addictive behavior despite the aversive consequences" (p. 415).

The addiction model is the framework for Overeaters Anonymous (OA), one of the most popular self-help programs for bulimia nervosa and for other commercial eating disorder programs patterned after the OA or "12-step" approach to chemical dependency. Malenbaum, Herzog, Eisenthal, and Wyshak (1988) have described many of the benefits of OA, including group support, "sponsorship" by someone who has achieved some measure of success, and the clear guiding philosophy originally applied to alcoholism in Alcoholics Anonymous. OA programs are aimed at achieving abstinence from compulsive overeating which is achieved, in part, by adhering to several behavioral axioms. Participants are usually advised to eat nothing beyond three meals a day, on the basis of the premise that certain foods are "addicting" and will trigger bouts of compulsive overeating (Malenbaum et al., 1988).

Although there are parallels between eating disorders and chemical dependency, there are serious theoretical and practical limitations to the comparison. Bemis (1985), and more recently Wilson (1991, 1993), have provided a thorough analysis of the topic, and only the salient points will be reviewed. The most obvious flaw in the application of the addiction model to overeating is that abstinence from food (unlike abstinence from alcohol) is obviously unrealistic, and recommending "controlled eating" is analogous to recommending controlled drinking, which is antithetical to the abstinence model applied to substance abuse (Bemis, 1985; Garner, 1985; Malenbaum et al., 1988; Wilson, 1991, 1993). The parallel breaks down further in trying to understand the nature of the compulsive overeater's addiction. Empirical evidence is lacking for the assertion that specific foods are addicting. Moreover, the OA explanation of compulsive overeating is completely inconsistent with the far more parsimonious understanding of binge eating, food preoccupations and food cravings as biological adaptations to chronic undernutrition (Garner, 1997; Garner, Rockert, et al., 1985; Wardle, 1987). Thus, to the degree that OA programs encourage "control" by avoiding certain foods while not deviating from three small meals a day (Garner, 1985), they may inadvertently collude with the bulimia nervosa patient's restrictive eating patterns. Unfortunately, these programs also reinforce the fear that normal eating will result in inordinate weight gain. Moreover, encouraging participants to avoid "forbidden foods" is inconsistent with the evidence from the treatment literature on the effectiveness of incorporating these foods into a daily eating plan (Rosen & Leitenberg, 1985).

While strongly encouraging abstinence from bingeing or vomiting is consistent with recommendations of other treatment approaches, the relative intolerance for "slips" in some abstinence oriented eating disorder programs may exacerbate the harsh, self-critical, and dichotomous thinking patterns that are already prominent among these patients (Bemis, 1985). The OA model also has been criticized for presenting compulsive overeating as an "incurable illness," a characterization that contradicts the growing literature on treatment success. Finally, whereas some patients find the spiritual orientation of the OA approach appealing, others may find it incompatible with their religious or moral beliefs. In Wilson's (1991) review of the addiction model of eating disorders, he decisively concludes that: (i) it does not address the core clinical features of eating disorders, (ii) it fails to account for the effects of dieting on behavior, and (iii) it may seriously undermine the effectiveness of treatment. Despite these criticisms, it is important to acknowledge that many find the OA model useful and effective. Clearly what is needed is research extending the one uncontrolled report in the literature (Malenbaum et al., 1988).

5.23.5.5 Cultural Factors

A complete understanding of eating disorders requires attention to the cultural forces selectively impinging on young girls and women in modern times. One of the most pernicious has been the intense pressure to diet and to engage in strict weight control in order to meet unrealistic standards for thinness (Garner & Garfinkel, 1980; Garner, Garfinkel, Schwartz, & Thompson, 1980). Young women today are totally immersed in the cultural admiration of a physical form for women that has little to do with the actual shape of most women in our society. The disconcerting result is a norm in which women report being dissatisfied with their shapes and to feeling guilty about eating even reasonable amounts of food. It has been increasingly recognized that dieting can play a direct role in causing a range of symptoms such as binge eating and mood disturbances (Garner, 1997; Garner, Rockert, et al., 1985; Polivy & Herman, 1985; Striegel-Moore, Silberstein, & Rodin, 1986). The values surrounding slenderness have become sufficiently embedded in our cultural value system that many of the symptoms required for eating disorders are not viewed as unusual or abnormal by members of the general public (Huon, Brown, & Morris, 1988). There is even some evidence that eating disorders may have developed a positive social stereotype and, in some instances, may be spread by social contagion (Bruch, 1985; Chiodo & Latimer, 1983). Recognition of the impact of cultural factors on norms related to dieting and weight control has led to the conclusion that eating disorders may develop in those without underlying personality disturbances or family dysfunction, although secondary disruption in both of these areas may be present by the time the person presents for an assessment (Garner, 1997). Much of current psychological theorizing related to eating disorders may be criticized for not accounting for these cultural factors or, when they are mentioned, not specifying the details of how they must be integrated into the understanding of the psychology of the disorder.

5.23.6 MULTIMODAL ASSESSMENT

Descriptive refinements along with advances in the areas of diagnosis, pathogenesis, and treatment have resulted in tremendous improvements in the technology of assessment (Crowther & Sherwood, 1997). While there is no universally accepted assessment protocol for eating disorders, there is a consensus on the value of a multimodal assessment approach based on the conceptualization of eating disorders as multidetermined and heterogeneous in nature.

The targets for assessment of the eating disorder patient can be divided into two main areas. First is specific psychopathology and behavioral patterns that define the core features of the disorders. Symptoms such as binge eating, extreme weight control behaviors, and stereotypic attitudes toward weight or shape fall into this category. Second is psychopathology not necessarily specific to eating disorder patients, but that has particular theoretical or clinical relevance. Examples include psychological features such as low self-esteem, perfectionism, fears of psychobiological maturity, poor impulse control, and reactions to sexual abuse. There are also more general associated features such as depression, anxiety and poor social functioning which are important aspects of the psychopathology.

5.23.6.1 Targets of Assessment

5.23.6.1.1 Body weight history

Athough body weight is not "psychopathology" *per se*, it is obviously a fundamental aspect of eating disorders. Determining the patient's current body weight and weight history provide essential diagnostic information. This information serves as a basis for exploring the central psychopathology of eating disorders which is the meaning body weight and shape has to the patient. Since amenorrhea is required for anorexia nervosa, menstrual history should be determined within the context of the weight history.

5.23.6.1.2 Binge eating

Binge eating is a key symptom in bulimia nervosa and binge eating disorder. It occurs in about 50% of cases presenting with anorexia nervosa. Thus, determining the presence or absence of binge eating is critical to diagnosis and treatment planning. The *DSM-IV* defines binge eating as having two main characteristics: (i) consumption of a large amount of food, and (ii) the experience of loss of control. Despite the definitional requirements, research has indicated a significant minority of eating disorder patients describe binges involving relatively small amounts of food. Moreover, in some cases there is no real loss of control. Thus, until there is agreement on the significance of size of binge episodes, it is recommended that assessments follow the system proposed in the eating disorder examination (below) for dividing episodes of overeating into four types based on amount of food eaten (large or small) and loss of control (present or absent). It is important to determine age of onset, frequency, and duration of binge eating episodes. Likewise, circumstances surrounding binge episodes (settings, times of day, social context, thoughts, and emotions) should be ascertained.

5.23.6.1.3 Extreme weight losing behaviors

The intensity of the dieting efforts and the types of weight losing behaviors employed can reflect psychopathology. A dieting history should pinpoint when dieting first began and its course over time. Information should be gathered regarding extreme weight control behaviors including self-induced vomiting, laxative and diuretic abuse, use of diet pills or other drugs to control appetite, use of emetics, chewing and spitting food out before swallowing, prolonged fasting, and excessive exercise. Diabetic patients may manipulate insulin levels and patients taking thyroid replacement hormone may alter their dosage to control body weight. Establishing the frequency (as well as the number of symptom free days) for vomiting, laxative abuse, and other extreme weight control behaviors is essential in determining the severity of the disorder and the need for medical consultation.

5.23.6.1.4 Psychopathology related to weight or shape

The psychopathology related to weight or shape has been described in various ways over the years including a drive for thinness, fear of fatness, shape and weight dissatisfaction, body size misperception, body image disturbance, and fears associated with physical maturity. Dissatisfaction with overall body shape and disparagement directed toward specific bodily regions are common in eating disorders and should be a focus of assessment. Some patients may actually overestimate their body size. Although research has shown that this is not unique to eating disorder patients, it may have clinical importance, particularly for emaciated patients. A critical psychopathological feature in anorexia nervosa and bulimia nervosa is that patients must be more than merely dissatisfied with their body; they rely on weight or shape as the predominant or even the sole criterion for judging their self-worth. This criterion has been made mandatory for a diagnosis of the two main eating disorders according to the *DSM-IV*. In anorexia nervosa, there is often a denial of the seriousness of a current low weight as well as intense fear of weight gain.

5.23.6.1.5 General psychopathology relevant to eating disorders

Eating disorder patients have been described as suffering from ineffectiveness feelings, low self-esteem, lack of autonomy, obsessionality, interpersonal sensitivity, introversion, poor relationship skills, social anxiety, dependence, perfectionism, fears of psychobiological maturity, poor impulse control, external locus of control, conflict avoidance, developmental pathology, failure in separation–individuation, vulnerability to substance abuse, interoceptive deficits, and idiosyncratic or dysfunctional thinking patterns. Complete psychological assessment should include these areas as well as evaluation of stable personality features, overall psychological distress, depression, anxiety, family functioning, history of sexual abuse, social and vocational adaptation, all of which may be relevant to the development and maintenance of these syndromes.

5.23.6.1.6 Psychopathology secondary to starvation

It may not be apparent from the initial assessment whether psychological distress, cognitive impairment, and behavioral symptoms signal fundamental emotional disturbance or are secondary elaborations resulting from weight loss and chaotic dietary patterns. Symptoms such as poor concentration, lability of mood, depressive features, obsessional thinking, irritability, difficulties with decision making, impulsivity, and social withdrawal have been identified in normal subjects undergoing semistarvation (Garner, 1997). Thus, these symptoms may reflect secondary effects of weight suppression rather than primary psychopathogy in eating disorder patients.

5.23.6.2 Assessment Methods

Various approaches to information gathering have been developed for eating disorders including clinical interviews, self-report measures, self-monitoring, direct behavioral observation, symptom checklists, clinical rating scales, the stroop test, and standardized test meals. The most commonly used methods are semistructured clinical interviews and self-report measures.

5.23.6.2.1 Clinical interview

Clinical interviews have been the primary method for gathering information on eating disorders. The Eating Disorder Examination (EDE, Cooper & Fairburn, 1987) is the most well validated and has generated a large body of research. It is an investigator based semi-structured interview for assessing psychopathology specific to eating disorders and is the current interview method of choice. Responses are organized on four subscales (restraint, eating concern, shape concern, and weight concern). The EDE can be used to arrive at a diagnosis, it has proven sensitive to treatment effects, and it defines different forms of overeating based upon amount of food eaten (large vs. small) and presence or absence of loss of control. The EDE has the advantages of allowing a more fine-grained appraisal of the specific psychopathology of eating disorders and permitting investigator probes to clarify the meaning behind responses to questions. Disadvantages of the interview include the fact that it takes an hour or more to administer, it requires a trained interviewer, and it is not suitable when anonymity or group administration are required.

5.23.6.2.2 Self-report measures

Various self-report instruments have been introduced to measure eating disorder symptoms. The two most widely used in clinical and research settings are the Eating Attitudes Test (EAT) and the Eating Disorder Inventory (EDI). The EAT is a widely used, standardized, self-report measure of eating disorder symptoms (Garner, 1997). A factor analysis of the original 40-item version resulted in a brief, 26-item measure of global eating disorder symptoms. The EDI is a standardized, multiscale instrument with a much broader focus (Garner, 1991). It comprises three subscales tapping attitudes and behaviors concerning eating, weight, and shape (drive for thinness, bulimia, body dissatisfaction) plus subscales assessing more general psychological traits or organizing constructs clinically relevant to eating disorders (ineffectiveness, perfection, interpersonal distrust, interoceptive awareness, maturity fears). The EDI-2 (Garner, 1991) added three new subscales to the original instrument (asceticism, impulse regulation, and social insecurity). The EAT and EDI have good psychometric properties and are sensitive to treatment effects. The EDI provides a psychological profile that can be useful in clinical situations.

Self-report measures have the advantages of being relatively economical, brief, easily administered and objectively scored. They are not susceptible to bias from interviewer–subject interactions and can be administered anonymously. The major disadvantage of self-report measures is that they are less accurate than interview methods, particularly when assessing ambiguous behaviors such as binge eating. They need to be supplemented by symptom frequency data derived by interview or a symptom checklist. Under some circumstances, symptom data gathered using self-report symptom checklist (e.g., Eating Disorder Symptom Checklist; Garner, 1991) can provide information pertinent to a diagnostic formulation. The different methods for assessing psychopathology in eating disorders have different aims, strengths, and weaknesses. The strategy adopted should be guided by the aims of the assessment and, whenever possible, convergent methods should be employed.

5.23.7 CLINICAL DECISION MAKING IN TREATMENT

The number of psychotherapeutic options available in treating eating disorders has expanded remarkably since the mid-1980s. The major approaches to psychotherapy have been well articulated along with a growing list of alternative forms of treatment (Garner & Garfinkel, 1997). The aim of the following section is to briefly review the major treatment options for eating disorders within the context of a decision-making paradigm for integration and sequencing of these treatments.

5.23.7.1 Integration and Sequencing of Treatments

The wisdom of considering integration of different psychotherapeutic procedures is increasingly evident with the demonstrated effectiveness of different forms of treatment (Garner & Needleman, 1997). The notion of applying different treatments to different eating disorder patients is not new and has formed the basis for multidimensional approaches to psychotherapy (Garner, Garfinkel, & Bemis, 1982). However, there has been more recent interest in "stepped-care," "decision-tree," or "integration" models which rely on set rules for the delivery of the various treatment options (Agras, 1993; Fairburn, Agras, & Wilson, 1992; Fairburn & Peveler, 1990; Garner, Garfinkel, & Irvine, 1986; Garner & Needleman, 1997; Tiller, Schmidt, & Treasure, 1993). These overlapping concepts of treatment delivery share the value system of nonallegiance to a single theoretical orientation; however, they have somewhat different points of emphasis.

Figure 3 illustrates a tentative decision-making paradigm for sequencing and integration of treatments for people with eating disorders. The various treatment options are represented by the boxes with sharp corners (hospitalization, family therapy, self-help, individual therapy, etc.) as well as questions that need to be addressed (boxes with curved corners) related to symptom areas, patient characteristics, or response to previous treatments in determining the treatment to be offered. It does not include all treatment alternatives but concentrates on those for which there is good clinical and/or empirical support. With this schematic in mind, the major approaches to treatment will be reviewed along with the clinical criteria for their integration and sequencing.

5.23.7.2 Hospitalization and Day Treatment

Hospitalization may be considered in the treatment of eating disorders in order to meet at least two different objectives: (i) simple medical stabilization, and (ii) a strategic step aimed at the recovery process (Garner & Sackeyfio, 1993). When aimed at simple medical stabilization in treating physical complications, hospitalization is a medical priority that does not require the commitment by the patient to recover from the eating disorder. This contrasts with hospitalization intended as an important step in the process of recovery from an eating disorder (Andersen, Bowers, & Evans, 1997). As part of recovery, hospitalization not only addresses the physical aspects of the disorder but also targets the psychological problems that maintain it. This requires every effort to enlist the patient's commitment to actively participate in every stage of the treatment process.

There are several general guidelines for hospitalization including: (i) weight restoration or interruption of steady weight loss in patients who are emaciated, (ii) interruption of bingeing, vomiting, and/or laxative abuse that pose medical risks or complications, (iii) evaluation and treatment of other potentially serious physical complications, and (iv) management of associated conditions such as severe depression, risk of self-harm, or substance abuse. On rare occasions, hospitalization may be required to "disengage" a patient from a social system that both contributes to the maintenance of the disorder and disrupts outpatient treatment. Thus, as indicated above (guideline (ii)), the first major treatment consideration is whether or not the eating disorder patient is in sufficient medical danger to require hospitalization. If a careful evaluation of the patient's prior treatment and current motivation for treatment leads to the conclusion that they are clearly unresponsive to psychological treatment, then it is appropriate to consider hospitalization for medical stabilization only and referral to out-

Figure 3 General guidelines for integration and sequencing major treatment options for eating disorder patients. Begin in the upper left corner with the question "is the patient in serious physical danger?" Further criteria for decision making, including symptom areas, patient characteristics, or response to previous treatments, are indicated by boxes with rounded corners (mostly on the left side of the figure). The treatment options are represented by boxes with sharp corners (hospitalization, family therapy, self-help, individual therapy, etc.). The figure does not delineate all treatment alternatives or all considerations for decision making. However, it does include the main interventions for which there is good clinical and/or empirical support and key variables to consider in determining the most appropriate type and intensity of treatment. (*Handbook of Treatment of Eating Disorders* (pp. 50–66), by D. M. Garner and L. Needleman, 1997, New York: Guilford Press. Copyright 1997 by Guilford Press. Reprinted with permission.)

patient medical maintenance discussed below. More typically there is reason for optimism about recovery from the eating disorder. In these cases, hospitalization can usually be brief, again aimed at medical stabilization, but with the addition of psychological counseling and followed by referral to outpatient psychotherapy. The most common exception to brief hospitalization is the emaciated anorexia nervosa patient for whom longer hospitalization is usually required to make steady headway in the renourishment process. It is generally pointless to negotiate with patients or insurance carriers around the duration of hospitalization required for weight restoration, since the time needed is relatively straightforward and easy to calculate. It is the number of weeks or months required to reach at least 90% of expected weight, gaining at a rate of about three pounds a week and assuming optimal compliance with the treatment program. Even though this is a time-consuming and expensive process, it is an economical alternative if it leads to recovery since a chronic eating disorder inflicts heavy price, both in monetary and emotional terms. At the same time, it is legitimate to question the validity or timing of a lengthy hospitalization aimed at renutrition if steady weight gain does not occur.

Another situation in which hospitalization may be necessary is when a patient has had a protracted period of outpatient treatment and is simply unable to make improvement without the structure and containment offered by the inpatient environment. Indefinite outpatient treatment may be fruitless or even deleterious in the sense that it inadvertently colludes with the patient's ambivalence about recovery. It is like years of insight-oriented psychotherapy with an elevator phobic without ever requiring a ride on an elevator. Without some exposure, the therapist cannot ever assist the patient in confronting fears associated with weight restoration. The patient may perceive the recommendation for hospitalization as a threat or as abandonment, but they should be reassured that it is a humane alternative to the tremendous emotional and financial expense of prolonged and unproductive outpatient therapy. Psychotherapy can only achieve modest goals in the presence of the severe limits imposed by dietary chaos or chronic starvation.

Day treatment or partial hospitalization is the preferred alternative to inpatient care for most patients (Kaplan & Olmsted, 1997). This level of care provides structure around meal times plus the possibility for intensive therapy, without requiring the patient to become totally disengaged from the supports and the therapeutic challenges outside of the hospital. Day treatment programs offer the distinct advantage of being more economical than full hospitalization. They can also provide a useful bridge between inpatient and outpatient care. There are various models for day treatment programs which generally share many features with inpatient programs. The major difference is that patients receive the therapeutic services but do not stay overnight. Inpatient treatment is still the preferred modality for patients who are seriously emaciated, require close medical monitoring, fail to progress in partial care, or are at serious risk of self-harm.

5.23.7.3 Outpatient Medical Management

Concluding that a patient is unresponsive to psychological treatment and then referring to an outpatient medical management (Figure 3) requires careful analysis and considerable reflection. However, there are some chronic or recalcitrant patients who have participated in various forms of treatment over the course of years and finally reach the point where they no longer want treatment for their eating disorder or they can agree that further psychotherapy has a very low probability of success. In these circumstances, psychotherapy aimed at recovery can be highly frustrating for the therapist and the patient alike, often leading to termination with inadequate follow-up plans. Patients are then reluctant to seek further assistance when their medical or psychological condition deteriorates. The key is determining if there really has been sufficient exposure to truly adequate treatment since patients can have extensive exposure to poor treatment or therapists who are not knowledgeable about eating disorders. If careful evaluation leads to the conclusion that the patient has had an adequate course of psychotherapy and (i) is not in imminent psychological or medical danger, (ii) is sufficiently symptomatic to suggest ongoing potential medical risk, and (iii) there is no clear rationale for further psychotherapy, then termination from psychotherapy may be very appropriate as long as it is made conditional on the patient agreeing to participate in ongoing "medical management" (Figure 3). Again, the goal of medical management is very different from psychotherapy. Rather than focusing on overcoming the eating disorder, it is aimed at maintaining medical and psychological stability. It can be conducted in an individual or a group format, meeting weekly with medical supervision. Body weight, electrolytes, and vital signs should be checked with appropriate referral to medical specialists, as needed. Patients derive the added benefits of group support and sharing with similarly afflicted patients. In some cases, these groups set the stage for renewed efforts to actively address the eating disorder symptoms.

5.23.7.4 Self-help and Guided Self-help

There are eating disorder patients at the other end of the severity spectrum who have relatively mild symptoms and who may experience marked improvement or complete recovery with self-help or education-based interventions. Self-help organizations for eating disorders have been very popular since the late 1970s (Baker-Enright, Butterfield, & Berkowitz, 1985). From the mid-1980s, there has been a remarkable increase in number of self-help books available for eating disorder patients and their families (Santrock, Minnett, & Campbell, 1994). Interest in testing the efficacy of self-help has been slower to develop, but there are now a number of studies indicating that some forms of self-help or guided self-help may be quite effective with some eating disorders (see Fairburn & Carter, 1997). As indicated in Figure 3 self-help is recommended for patients with less severe eating disorders symptoms. While self-help is not sufficient as the sole treatment for most patients, there is a significant subgroup who benefit from this extremely economical intervention.

5.23.7.5 Psychoeducation

Figure 3 indicates that psychoeducation should be considered for bulimia nervosa patients with milder symptoms. As will be reviewed in a later section, there have been a number of research studies providing empirical support for the utility of educational approaches in the treatment of eating disorders. Education was originally recommended as part of early descriptions of cognitive behavioral treatment for eating disorders based on the premise that certain faulty assumptions evinced by patients were maintained, at least in part, by misinformation (e.g., Garner & Bemis, 1982). One early psychoeducational primer (Garner, Rockert et al., 1985) emphasized the conflict between the cultural pressures on women to diet and biological compensatory mechanisms which tend to defend a "set point" for body weight. The primer has been updated (Garner, 1997) and provides background for challenging society's harsh standards for women to be thin, education regarding the biology of weight regulation, recommendations for establishing regular eating patterns, and methods for interrupting bingeing and purging. There seems to be general agreement on the utility of incorporating psychoeducation into most treatment approaches for eating disorders. For people with mild eating disorder symptoms (Figure 3), guided self-help or educational groups should be considered as an economical and potentially effective option before proceeding to more costly interventions.

5.23.7.6 Family Therapy

Family therapy is the initial treatment choice for patients who are young and/or living at home (Figure 3). Family therapy should also be regarded as a desirable adjunct to individual therapy with older patients living outside of the home, particularly when family conflicts predominate. For young patients, there are practical as well as theoretical reasons for recommending family therapy. From a strictly practical point of view, the patient shares her home with her parents or guardians who are responsible for her well-being. Parents have the potential to provide powerful directives in support of therapeutic goals. Regardless of theoretical orientation of treatment, family members need assistance in dealing with a young eating disordered patient.

Family therapists have argued convincingly that eating disorders may reflect certain conflicts, dysfunctional roles, or problematic interactional patterns within the family (Dare & Eisler, 1997; Minuchin et al., 1978; Selvini-Palazzoli, 1974). The following are some of the more common problematic themes.

(i) Denial regarding the seriousness of the eating disorder may be manifest by the identified patient and/or the parents. Both the patient and parents may need assistance in accurately labeling the eating disorder which involves neither minimizing or exaggerating the significance of certain symptomatic behaviors.

(ii) Particularly with younger patients, parents may need help in developing an effective parenting style. Guilt and fear may have prohibited them from being firm and effective in establishing guidelines for behavior consistent with recovery. Parents should be encouraged to maintain usual expectations in areas unrelated to food and eating (bedtime, chores, language, treatment of siblings) except when unrealistic parental expectations are directly contributing to the problem. Treatment recommendations should be consistent with the family's value system and appropriate to the developmental stage of the child.

(iii) Parents may need assistance in accepting the patient's need for autonomy and self-expression through traits, interests, and values that may deviate from expectations within the family.

(iv) Under certain circumstances, parental attitudes about weight, shape, thinness, or "fitness" may be inappropriate. Inappropriate family eating patterns, beliefs about food or eating rituals should be identified, and practical interventions need to be designed that address areas of potential conflicts.

(v) An eating disorder can deflect members of the family away from potentially threatening developmental expectations emergent in the transition to puberty. It can function as a maladaptive solution to the adolescent's struggle to achieve autonomy in a family where any move toward independence is perceived as a threat to family unity. It can also become a powerful diversion enabling the parents and the child to avoid major sources of conflict.

(vi) The identified patient's symptoms may be functional within a disturbed family context and the meaning systems that underlie the resulting interactional patterns need to be identified and corrected. Problematic family interactional patterns need to be addressed such as "enmeshment," overprotectiveness, inadequate mechanisms for resolving conflicts, and inappropriate parent–child allegiances that undermine the marital relationship (Minuchin et al., 1978).

Even when family therapy is not the primary mode of treatment, it may be appropriate to integrate family therapy into the longer-term treatment plan. It can be a valuable adjunct to individual therapy in addressing trauma, such as sexual abuse, within the family (Andersen, 1985; Crisp, 1970; Garner et al., 1982; Wooley & Lewis, 1989).

5.23.7.7 Cognitive Behavioral Therapy

Cognitive behavioral therapy (CBT) has become the standard treatment for bulimia nervosa and forms the theoretical base for much of the treatment of anorexia nervosa. The empirical support for CBT in the treatment of eating disorders will be summarized in a later section. As indicated in Figure 3, CBT should be considered the treatment of choice for patients whose age does not mandate family therapy, and whose symptoms are moderate to severe.

The CBT for bulimia nervosa developed by Fairburn and colleagues (Fairburn, 1985; Fairburn, Marcus, & Wilson, 1993) has the following major points of emphasis: (i) self-monitoring of food intake, bingeing, and purging episodes as well as thoughts and feelings which trigger these episodes; (ii) regular weighing; (iii) specific recommendations such as the introduction of avoided foods and meal planning designed to normalize eating behavior and curb restrictive dieting; (iv) cognitive restructuring directed at habitual reasoning errors and underlying assumptions that are relevant to the development and the maintenance of the eating disorder; and (v) relapse prevention.

CBT is also effective in stabilizing the eating patterns of obese individuals who experience recurrent episodes of binge eating (Agras et al., 1992; Telch Agras, Rossiter, Wilfley, & Kenarely, 1990; Wilfley et al., 1993). The results with binge-eating disorder patients are promising; however, the long-term effectiveness of CBT with this group remains unclear.

In the case of anorexia nervosa, CBT has been recommended largely on clinical grounds (Garner, 1986, 1988; Garner & Bemis, 1982; 1985; Garner & Rosen, 1990; Garner et al., 1997; Vitousek & Orimoto, 1993). Case studies and preliminary research provide some grounds for optimism (Channon, DeSilva, Hemsley, & Perkins, 1989; Cooper & Fairburn, 1984); however, current data are insufficient to warrant meaningful conclusions regarding effectiveness.

There are many areas of overlap between the versions of CBT offered for anorexia and bulimia nervosa; however, there are also important differences that have implications for clinical care (Garner et al., 1997). A major focus for both disorders is the patient's underlying assumption that "weight, shape, or thinness can serve as the sole or predominant referent for inferring personal value or self-worth" (Garner & Bemis, 1982, p. 142). Fear of body-weight gain is a central theme for both anorexia and bulimia nervosa; however, most bulimia nervosa patients can be reassured that treatment will probably result in little weight gain. In contrast, in anorexia nervosa, therapeutic strategies must be aimed at actual weight gain in the face of the implacable wish to maintain a low weight. Establishing a sound and collaborative therapeutic relationship is particularly important in anorexia nervosa since it becomes a fulcrum for gradually helping the patient to relinquish the myriad of ego-syntonic symptoms. As indicated on Figure 3, CBT is modified for anorexia nervosa. It is typically longer in duration and the targets for cognitive interventions are broad, encompassing a wider range of personal and interpersonal subject domains than typical for bulimia nervosa (Garner et al., 1997). This is to address the marked deficits impeding normal psychosocial functioning in many of these patients. Thus, cognitive interventions are aimed not only at beliefs that maintain extreme dieting and chronic weight suppression but also at fundamental assumptions associated with interpersonal conflicts, feelings of ineffectiveness, struggles with autonomy, and fears associated with psychosocial development (Garner & Bemis, 1982; Garner & Rosen, 1990; Garner et al., 1997; Vitousek & Orimoto, 1993; Vitousek & Ewald, 1993). Components of interpersonal therapy and family therapy are often integrated into longer-term CBT for anorexia nervosa (see Figure 3). In the subset of anorexia nervosa patients who do not engage in binge eating, and those who show no obvious serious physical complications, there may be extraordinary resistance to complying with the therapeutic objectives of weight gain. However, as long as there is gradual improvement in symptoms (Figure 3), outpatient therapy is recommended; however, if the patient's condition deteriorates, hospitalization must be considered. Outpatient medical management (groups) should be considered if there is a protracted therapeutic impasse. This often takes the form of apparent psychological insights that invariably fail to translate into symptomatic change.

5.23.7.8 Interpersonal Therapy

Since the mid-1980s, the prevailing view was that CBT's effectiveness with eating disorders was tied to cognitive and behavioral methods aimed specifically at overconcern about weight and shape which are responsible for restrictive dieting and extreme weight controlling behaviors. Changing these attitudes presumably relaxed restrictive dieting and relieved the biological tension created by chronic attempts to suppress body weight. However, a series of studies using interpersonal psychotherapy (IPT), adapted to bulimia nervosa, has prompted re-examination of earlier speculations regarding the specific mechanisms of action in the treatment of binge eating (Fairburn et al., 1995). This is because IPT does not directly focus on eating problems. IPT was originally proposed by Klerman, Weissman, Rounsaville, and Chevron (1984) as a short-term treatment for depression. The IPT treatment process is divided into three stages (Fairburn, 1997). The first stage involves the identification of the interpersonal problems that led to the development and maintenance of the eating problems. The second stage consists of a therapeutic contract for working on these interpersonal problems. The final stage addresses issues related to termination. Fairburn et al. (1991) found IPT somewhat less effective than CBT at the end of treatment; however, patients who received IPT gradually improved during the follow-up period so that after one year, both treatments were equally effective (Fairburn et al., 1993). These findings are maintained over the longer term with patients recieving CBT or interpersonal therapy doing significantly better than those receiving behavior therapy (Fairburn et al., 1995). This pattern of improvement during follow-up was not found in a study of another very different form of interpersonally oriented therapy, supportive-expressive therapy (Garner et al., 1993). These findings suggest that the IPT used by Fairburn et al. contains specific therapeutic ingredients that facilitate change. Further support for the effectiveness of IPT comes from Wilfley et al. (1993) in a study of nonpurging bulimic patients, many of whom presented with obesity. They found both CBT and IPT equally effective in reducing binge eating assessed both at the end of treatment and at one year follow-up.

The evidence that certain interpersonal therapies are as effective with binge eating as CBT has implications for the decision process illustrated in Figure 3. It could be argued that there should be no priority for either IPT or CBT as the initial treatment of choice for bulimia nervosa since both treatments are equally effective in the long-term. Certainly, a therapist well trained in one of the interpersonal therapies described by Fairburn and colleagues should not be encouraged to abandon this form of treatment in favor of CBT. However, we are still inclined to recommend CBT as the preferred initial treatment at this time since it has been shown to have a more rapid effect on symptoms. Moreover, the efficacy of IPT for bulimia nervosa has been demonstrated in just one center compared to many studies in support of CBT. If the findings from the Oxford trials are replicated in other centers, then IPT may become another "standard" initial treatment for bulimia nervosa. At this time, there is no empirical basis for suggesting that IPT should be differentially applied to patients on the basis of premorbid features such as interpersonal conflicts. However, integrating IPT into treatment should be considered for bulimia nervosa patients who fail to respond favorably to an initial course of CBT when interpersonal conflicts predominate according to Figure 3. The IPT orientation should also be a leading candidate for integration into longer term psychotherapy for anorexia nervosa patients or for others with persistent symptoms.

5.23.7.9 Psychodynamic Therapy

There have been no controlled comparisons between longer-term psychodynamic psychotherapy and other forms of treatment; however, dynamically oriented treatments have been well articulated for eating disorders and may be recommended on clinical grounds when other short-term treatments are ineffective (Figure 3). Psychodynamic treatment for eating disorders may be roughly divided into two schools of thought. The first presumes eating disorders do not require fundamental modifications to orthodox dynamic interventions since neither the symptoms nor the disorders represent a unique underlying process. The second conceptualization implies that eating disorders are distinctive in that they require major modifications to traditional dynamic therapy in order to meet the special psychological needs of the patient. There has been considerable movement among dynamically oriented writers toward integrating psychodynamic therapy with active symptom management principles in the treatment of both anorexia nervosa and bulimia nervosa (Bruch, 1973; Casper, 1982; Crisp, 1980, 1997; Goodsitt, 1985, 1997; Stern, 1986; Strober, 1997; Strober & Yager, 1985). However, there are still some who espouse a traditional interpretive framework (Lerner, 1993; Sands, 1992; Sugarman, 1991). At this time, we recommend the integration of longer-term dynamically oriented therapy be considered as an alternative to long-term CBT for patients who fail less expensive approaches.

A new generation of feminist therapists deviate from the traditional views by incorporating the growing literature on the psychology of women into dynamic formulations regarding the etiology and treatment of eating disorders (Fallon, Katzman, & Wooley, 1994; Fallon & Wonderlick, 1997; Katzman, 1994; Kearney-Cooke & Striegel-Moore, 1997; Perlick & Silverstein, 1994; Steiner-Adair, 1994; Striegel-Moore, 1994). They have highlighted the importance of addressing issues such as sexual abuse and other forms of victimization in the development, maintenance, and treatment of eating disorders. Even though controlled studies are lacking at this time, the highly evolved conceptual framework presented by these dynamic-feminist treatment approaches warrants their consideration when abuse is identified during the course of assessment or treatment (Figure 3). At this time, the therapist's orientation, rather than the special needs of the patient, probably determine the decision to apply feminist therapy for eating disorders. However, many of the views articulated by feminist therapists have influenced the applications of other forms of therapy. There are some eating disorder patients, because of the nature of their predisposing and perpetuating factors, who should receive feminist therapy as the treatment of choice.

5.23.7.10 Pharmacotherapy

Figure 3 indicates medication should be considered for patients with bulimia nervosa or binge-eating disorder who fail an initial trial of cognitive behavioral therapy but is generally not indicated for anorexia nervosa. There have been many well-controlled trials since the mid-1980s indicating the effectiveness of some antidepressant medications for bulimia nervosa and the research evidence will be reviewed in detail in a later section. However, in reviewing the research in the field, Raymond et al. (1994) have suggested that medication should not be "the primary mode of therapy with patients with bulimia nervosa" (p. 241). This conclusion is based on the following observations: (i) psychological interventions have been shown to be very effective, (ii) there are high drop-out rates reported in most medication studies, (iii) there are risks of drug side effects, and (iv) data suggest high relapse rates with drug discontinuation. Based on a multisite collaborative study (Fluoxetine Bulimia Nervosa Collaborative Study Group [FBNC], 1992), fluoxetine hydrochloride (Prozac) is currently the first choice for the treatment of bulimia nervosa (daily dosages of 60 mg were generally superior to 20 mg) and probably should be used at least as an adjunct to psychotherapy in many cases failing in a course of adequate psychological treatment. Tricyclic antidepressants may be an alternative for some patients failing a course of fluoxetine, but side effects, high drop-out rates, and greater lethality with overdose may be a source of concern when treating some patients (Leitenberg et al., 1994; Mitchell et al., 1990). Similarly, monoamine oxidase inhibitors (MAOIs) may be useful in a small minority of patients who fail using fluoxetine and tricyclics. There is some evidence that patients who fail on one tricyclic may benefit from changing to an alternative medication (Mitchell, Raymond, & Specker, 1993). Alternatively, the specific decision to not prescribe medication may be therapeutic in some cases (Raymond et al., 1994).

There is still little evidence for change in the early recommendations that pharmacotherapy has a very limited value with emaciated anorexia nervosa patients and should never be the sole treatment modality (Garfinkel & Garner, 1982). Occasionally patients may benefit from medication to deal with overwhelming anxiety, severe depression or intolerable gastric discomfort after meals, but this only applies to a small minority of patients (Andersen, 1985; Garfinkel & Garner, 1982; Garfinkel & Walsh, 1997).

Thus, in the decision-tree approach for treating eating disorders, antidepressant medication should be considered as an adjunct or possibly an alternative for bulimia nervosa patients who fail to respond to psychosocial therapies or for those whose affective symptoms are clearly impeding progress in other forms of treatment. Drug treatments have generally not proven effective for anorexia nervosa.

5.23.8 PSYCHOLOGICAL TREATMENT RESEARCH

5.23.8.1 Treatment Research on Anorexia Nervosa

Evaluation of treatment response would be aided by an understanding of the natural history of the disorder. While there are no studies of the actual natural history of anorexia nervosa, Theander (1985) has provided an estimate from a long-term follow-up study of 94 patients seen in the early 1960s and thus, probably received treatment that was quite crude compared to modern methods. The patients were evaluated in 1966 (after a mean observation time of 15 years since the onset of the disorder) and again in 1984 (after a mean observation time of 33 years). Table 1 presents outcome status for the sample five, 15, and 33 years after the onset of the disorder and indicates an aggregation over time of patients into the recovered and deceased categories. Of the patients who died, one-third committed suicide and two-thirds died of complications from their disorder. The data in Table 1 dramatically illustrate that the evaluation of outcome in anorexia nervosa varies depending on when the assessment is performed and that, after many years of illness, patients tend either to improve or to die.

Since 1953 there have been more than 60 follow-up studies of anorexia nervosa (Eckert, Halmi, Marchi, Grove, & Cosby, 1995; Fichter & Quadflieg, 1995; Steinhausen, Rauss-Mason, & Seidel, 1991); however, there are few controlled trials comparing different treatment approaches. There is considerable variation in the outcomes reported across these follow-up reports which could be expected given differences among methodologies and treatment settings.

The major outcome criteria used in these follow-up studies have been diagnosis, weight, menses, eating behavior, general psychological functioning, and psychosexual status. Usually a global outcome (good, moderate, poor, death) is derived from some composite of these variables. The mortality rates have varied from 0% to 22%, with over half of the studies reporting deaths in 4% or fewer patients (Garfinkel & Garner, 1982; Herzog, Keller, Lavoni, & Ott, 1987; Sullivan, 1995). The mortality rates for anorexia nervosa are two times higher than for any other psychiatric disorder and more than 12 times higher than all-cause mortality for females. Although the definition of "recovery" has been ambiguous, between 12% and 87% of patients appear to be free of eating disorder symptoms at follow-up (Hsu, 1996). Consistent with the report by Theander (1985), studies of relatively brief follow-up find fewer patients who are recovered or deceased, with most patients congregating in the moderate to poor outcome. More patients recover and the number of deaths increase as the follow-up is extended.

Some patients can be considered fully recovered at follow-up while others who recover in terms of weight and eating remain disturbed in other areas of functioning. Casper (1990) reported that about 25% of patients classified as having a good outcome in an 8–10-year follow-up were still weight preoccupied and depressed. In a study of 60 anorexia nervosa patients followed 5–14 years after presenting for treatment, Toner, Garfinkel, and Garner (1986) found that 38% were asymptomatic, 27% improved, 27% unchanged, and 8% deceased. While a significant proportion of the sample met *DSM-III* criteria for affective (34%) or anxiety disorders (47%) in the year prior to follow-up, those in the asymptomatic group had scores equivalent to noneating disorder controls on most measures of psychosocial functioning. Rastam et al. (1995) followed a sample of anorexia nervosa patients six years after onset and found that most cases no longer met criteria for the original eating disorder, but many developed bulimia nervosa or atypical eating disorders. In a 12-year follow-up study of 69 hospitalized anorexia nervosa patients, Herzog, Schellberg, and Deter (1997) found that 50% of patients did not improve until more than six years after the first inpatient treatment.

One of the most striking observations regarding outcome is the relatively good prognosis for pediatric compared with older samples. In a summary of pediatric studies, Garfinkel and Garner (1982) indicated that the outcome status of patients in follow-up studies conducted before 1974 were quite similar to that reported in the literature on older adolescents and adults. However, later pediatric outcome studies indicate a very positive prognosis with recovery rates of between 76% and 87% (Cantwell, Sturzenburger, Burroughs, Salkin, & Green, 1977; Goetz, Succop, Reinhart, & Miller, 1977; Martin, 1985; Minuchin et al., 1978; Silverman, 1974). Steinhausen and Glanville (1983) present somewhat less optimistic findings from a 9.4-year follow-up of patients presenting between the ages of 11 and 17. They report that only 30% of their sample could be considered symptom free at follow-up. Similarly, only 50% of the early onset cases ($N = 18$) followed by Hawley (1985) after a mean of 8.7 years were classified as having a good outcome. Theander (1996) reviewed the literature on early onset anorexia nervosa and

Table 1 Long-term outcome in anorexia nervosa.

	Years after onset of the disorder		
Outcome status	*5 years* (%)	*15 years* (%)	*33 years* (%)
Good	55	63	76
Intermediate	19	17	1
Poor	18	7	6
Death	8	13	18

Source: Theander (1985), adapted by permission.

found that there are relatively more boys among patients with extremely early onset. He also reported that early onset predicted better outcome, but long-term outcome is unfavorable for many early onset cases.

Follow-up reports indicating that early age of onset confers a positive prognosis (cf. Garfinkel & Garner, 1982; Herzog, Keller, & Lavori, 1988) as well as the variable, but generally positive, outcome in a number of pediatric samples has led to the interest in family therapy in research studies on anorexia nervosa. In the first controlled trial examining two forms of treatment, Russell et al. (1987) compared family and individual supportive therapy for both anorexia nervosa and bulimia nervosa. It was concluded that family therapy was superior for patients whose disorder was not chronic and that had begun before the age of 19. A somewhat more tentative finding was that individual therapy yielded better results with older patients.

In another study of family treatment, Robin, Siegel, and Moye (1995) randomly assigned 22 adolescent anorexia nervosa patients to 16 months of either behavioral family systems therapy or ego-oriented individual therapy and found that both treatments had a positive effect on body mass index, menstruation, and family interactional patterns. There was no consistent pattern of differential treatment effects; however, the relatively small sample size used in the comparison makes it difficult to detect treatment differences.

Although family intervention was not the object of the study, Crisp et al. (1991) provided collateral evidence for the utility of family intervention in a controlled study in which 90 anorexia nervosa patients were randomly assigned to one of three types of treatment (or referral back to the community). The three treatment conditions were: (i) intensive inpatient treatment followed by 12 sessions of outpatient therapy, (ii) 12 outpatient individual and family psychotherapy sessions, and (iii) 10 outpatient group psychotherapy sessions (both for patients and parents separately). All three active treatments were accompanied by dietary counseling aimed at gradual weight restoration. Outcome was assessed at the end of treatment and at one-year follow-up. Of the 20 control group patients referred back to the community, 14 received some form of treatment and six were untreated. At one year, there were no significant differences between the three active treatment conditions in weight gain, return of menses, or important aspects of psychosocial functioning. Surprisingly, although the inpatient treatment was more intensive (several months of inpatient care followed by 12 outpatient sessions), presumably much more costly, and delivered as the treatment of choice by Crisp and colleagues for years, it was no more successful than the strictly outpatient approaches. In terms of weight gain at follow-up, inpatient treatment was not superior to the controls. Moreover, the inpatient treatment had a much higher rate of noncompliance (40%) compared to the outpatient conditions (10–15%). A two-year follow-up of this same sample (Gowers, Norton, Halek, & Crisp, 1994) indicated that the positive outcome with the outpatient treatment package was sustained. Thus, the results of this major study challenge the assumption that "more treatment is better" and that inpatient treatment is the treatment of choice for anorexia nervosa.

More evidence for the efficacy of less intensive treatment comes from a study by Treasure et al. (1995) in which 30 anorexia nervosa patients were randomly assigned to either cognitive analytical therapy (CAT) or educational behavioral therapy. At one year, both of these outpatient treatments led to significant weight gain. Patients assigned to the CAT reported significantly greater subjective improvement; however, there were no treatment group differences in other outcome parameters. All these findings are summarized in Table 2.

The relatively small number of carefully controlled trials of treatments for anorexia nervosa may relate, in part, to the protracted, complicated, and variable course in the treatment of the disorder. Many cases require one or more periods of hospitalization at various points during a lengthy and fluctuating recovery process. Since this may require numerous transitions between inpatient and outpatient treatment staff over an extended period of time in response to the patient's changing nutritional status, it is difficult to design a rigorously controlled study protocol suitable for the range of patients presenting for treatment.

5.23.8.2 Treatment Research on Bulimia Nervosa

In contrast to the paucity of controlled trials with anorexia nervosa, there have been more than 25 controlled studies evaluating the efficacy of different treatment approaches to bulimia nervosa (for reviews see Garfinkel & Walsh, 1997; Garner, Fairburn, & Davis, 1987; Mitchell, Raymond, & Specker, 1993). The majority of these studies have involved comparing different forms of treatment or identifying active ingredients within the more successful treatment packages (primarily cognitive-behavioral) using a dismantling approach. Most

treatment packages have been between 10 and 18 weeks in duration, delivered in either a group or an individual format (cf. Garner et al., 1987; McKisack & Waller, 1997). It is evident from these and other studies that treatment can lead to statistically and clinically significant reductions in bingeing, vomiting, and other associated symptoms.

A number of comparative treatment studies of bulimia nervosa that provide very encouraging findings are summarized in Table 3 (see Mitchell et al., 1993 for earlier studies). It is evident from this that CBT, as well as certain other forms of treatment with which it has been compared, lead to marked reductions in bingeing and vomiting. In a long-term prospective follow-up of 91 eating disorder patients from two randomized controlled trials involving CBT, behavior therapy (BT), and focal interpersonal therapy (FIT), Fairburn et al. (1995) found that those received BT did poorly while bulimia nervosa patients who received CBT or FIT did markedly better. Compared to subjects in the BT condition, those in the FIT were twice as likely to be in remission (defined as no longer meeting a *DSM-IV* diagnosis for an eating disorder) and those in the CBT condition were more than three times as likely to be in remission. Similarly, about half of the patients who received CBT or FIT were completely abstinent from all key behavioral symptoms such as binge eating, vomiting, and laxative and diuretic abuse compared to 18% of those receiving BT.

Agras and colleagues (1992, 1994) compared desipramine, CBT, and their combination (with the drug withdrawn at either 16 or 24 weeks) and found that the combined drug and CBT treatment was superior to the other conditions as long as the medication was continued for at least 24 weeks. The finding that the combined treatment was more effective than 16 and 24 weeks of medication alone suggests that the CBT may be important in preventing relapse once medication is withdrawn. In the 1994 follow-up study, both the CBT and the combined 24-week treatment were superior in reducing binge eating to desipramine given for 16 weeks. This study supports earlier research indicating that medication alone is not the most effective treatment for bulimia nervosa but, contrary to an earlier study (Mitchell et al., 1990), it provides important data suggesting that antidepressant therapy may add significantly to the effects of CBT.

There have been a number of empirical studies of the effectiveness of educational and self-help treatments in bulimia nervosa. Educationally-oriented treatment seems to have remarkable impact on behavior for some patients, although the overall treatment results are not as potent as some of the more intensive CBT interventions (Connors, Johnson, & Stuckey, 1984; Huon & Brown, 1985; Wolchik, Weiss, & Katzman, 1986). Ordman and Kirschenbaum (1985) compared CBT to a "brief intervention wait-list" that consisted of just three assessment sessions and minimal intervention. A study comparing the presentation of this educational material in a group "classroom" format (five 90-minute sessions during a one-month period) with individual CBT indicated, for the least symptomatic 25–45% of patients in the sample, both treatments were equally effective on important measures of outcome (Olmsted, Davis, Garner, Eagle, & Rockert, 1991). Nutritional counselling or nutritional management (Beaumont, O'Connor, Touyz, & Williams, 1987) overlaps with the psychoeducational approach described above. Laessle et al. (1991) compared nutritional management (NM) with stress management and found both treatments led to marked improvement in eating symptoms and general psychopathology at the end of treatment and at a 12-month follow-up. However, NM produced a significantly more rapid reduction in binge eating, greater abstinence rates, and greater improvements on some measures of psychopathology.

Huon (1985) was the first to test the effectiveness of a self-help program. Binge eating subjects were recruited from a woman's magazine article and 32% who followed a self-help manual were symptom free at six-month follow-up compared to only 7% of a comparison group. Two later studies have shown short-term benefits of following a self-help manual but neither presented follow-up data (Schmidt et al., 1993; Treasure et al., 1994). In contrast to "pure" self-help, Cooper, Coker, and Fleming (1995) have shown that self-help, supervised by a professional, can be sufficient for some patients. At a four- to six-month follow-up of 82 patients, 16 (20%) had dropped out of the program, and 22 (33%) of those remaining had not binged or vomited over the past month (Cooper et al., 1995). Thus, while self-help is not sufficient as the sole treatment for most patients, there is a significant subgroup who benefit from this extremely economical intervention.

While there has been overall optimism regarding the efficacy of CBT, it again must be emphasized that improvement also has been observed with other forms of treatment. Significant reductions in bingeing and vomiting, as well as associated symptoms, have been found with nondirective (Kirkley, Schneider, Agras, & Bachman, 1985), short-term focal (Fairburn,

Kirk, O'Connor, & Cooper 1986; Fairburn et al., 1995), and supportive–expressive therapy (Garner et al., 1993). Understanding the active ingredients of some of these treatments is impeded by the fact that some included techniques such as self-monitoring, meal planning, education regarding the untoward effects of dieting, and behavioral contracting, which are generally considered as more conceptually aligned with CBT. Thus, it remains unclear whether the observed changes in behavior are attributed to the "psychological" components of the treatment or to the dietary management. In a comparison of bulimia nervosa treatment studies using dietary management with those that did not, Laessle, Zoett, and Pirke (1987) concluded that dietary management was associated with superior results. Further support for this hypothesis comes from a study indicating very poor outcome with a 12-week psychodynamically oriented group program that did not incorporate dietary management (Frommer, Ames, Gibson, & Davis, 1987). Nevertheless, there have been two studies of treatments for bulimia nervosa that did not emphasize dietary management (Fairburn et al., 1995; Garner et al., 1993) indicating that dietary management may not be essential for change in eating disorder symptoms.

In summary, a number of carefully controlled studies demonstrated that many patients derive benefit from either individual or group treatment and that CBT tends to perform better than drug and other psychological treatments. Dietary management may enhance the effectiveness of treatments of varying orientations. Since it is evident that not all patients improve with CBT, it is important to consider other treatment options, perhaps sequenced in a systematic manner, as part of a multidimensional model of treatment.

5.23.9 PSYCHOPHARMACOLOGICAL TREATMENT RESEARCH

A wide variety of medications have been tried with eating disorders and while they can play a role in helping some people, they should rarely become the exclusive mode of treatment (Garfinkel & Garner, 1987; Garfinkel & Walsh, 1997; Raymond et al., 1994). According to the decision-tree approach for treating eating disorders (Figure 3), antidepressant medication should be considered as an adjunct or possibly an alternative for bulimia nervosa patients who fail to respond to psychosocial therapies or for those whose affective symptoms are clearly impeding progress in other forms of treatment. Antidepressants have an even more limited role in the treatment of anorexia nervosa. With this general recommendation in mind, an overview of research on drug treatments will presented.

5.23.9.1 Treatment Research on Anorexia Nervosa

Historically, a variety of medications have been studied for their efficacy in promoting weight gain in women with anorexia nervosa. The rationale for trying many of the medications was based more on clinical observations than on a thorough understanding of the physiological mechanisms involved with this disorder. Unfortunately, we are still at a novice stage in our understanding of the physiological mechanisms that may contribute the development and maintenance of anorexia nervosa. Thus, although many medications have been tried in treating anorexia nervosa, few offer promise.

One class of medications that have been studied in the treatment of anorexia nervosa is antipsychotics. The rationale behind their use was the belief that the disturbed thinking regarding weight and shape, a cardinal feature of this disorder, may be a form of delusional thinking. Also, it was noted that dopamine mediates feeding and often people taking dopamine antagonists will experience weight gain. However, two double blind, placebo-controlled trials utilizing antipsychotic (pimozide and sulpiride) medications showed no statistically significant effects on weight (Vandereycken, 1984; Vandereycken & Pierloot, 1982).

A depressed mood is often associated with anorexia nervosa, and, as mentioned earlier, this is due most often to the effects of starvation. Given this, and that people treated with tricyclic antidepressants often experience an increase in appetite and weight gain, antidepressants have been utilized in treating anorexia nervosa. The results of open trials with antidepressants were promising; however, double-blind placebo-controlled studies yielded mixed results. Lacey and Crisp (1980) and Biederman et al. (1985) did not find significant effects on weight gain with either clomipramine or amitriptyline, respectively. Halmi, Eckert, LaDa, and Cohen (1986), however, did find that patients taking amitriptyline gained weight faster than those on a placebo. Substantial side effects from the amitriptyline were also noted.

One study reports on the effectiveness of lithium in treating anorexia nervosa (Gross et al., 1981). Again, the rationale for trying lithium was based on clinical observations of mood disturbances with anorexia nervosa and the weight gain experienced by many people who are prescribed lithium. The results of this study showed that the group of women with anorexia nervosa prescribed lithium did gain weight at a slightly faster rate, but that this was not statistically significant. Additionally, use of lithium may be problematic with this population due to frequent fluid imbalances if the person is purging.

Cyproheptadine, a serotonin and histamine antagonist, often used to treat allergies, has also been studied for its efficacy in treating anorexia nervosa. Cyproheptadine is a medication that is relatively free of side effects and promotes weight gain in some people who are prescribed it for allergies. Additionally, inhibiting serotonin transmission is believed to stimulate appetite. Thus, three controlled trials using cyproheptadine in treating anorexia nervosa were undertaken in the 1970s and 1980s. Two of the studies showed no significant effect on weight gain over placebo (Goldberg, Halmi, Eckert, Casper, & Davis, 1979; Vigersky & Loriaux, 1977). Halmi et al. (1986), utilizing a higher dosage, found that women with anorexia nervosa treated with cyproheptadine reached their goal weights an average of 10 days faster than those on placebo. This result was true only for the participants with the restricting subtype of anorexia nervosa, however, and the cyproheptadine was actually associated with delayed weight gain in those participants with the binge-purging subtype of anorexia nervosa. Moreover, there is little evidence to suggest that speed of weight gain is positively related to long-term recovery from anorexia nervosa.

Thus, the controlled trials of various medications designed to increase weight gain in women with anorexia nervosa have been generally disappointing. The practice guidelines for treating anorexia nervosa published by the APA (1993), indicate that medications should not be used routinely with this population. If an individual continues to experience mood disturbances following weight restoration, it is recommended that antidepressants be considered. Given that this is a volume that addresses clinical issues in children and adolescents, it should be noted that to date, no controlled trials of any medications reviewed here have been conducted with younger populations.

A more promising lead has been found when the focus is shifted from weight gain to relapse prevention in anorexia nervosa. Kaye, Guirtsman, George, and Ebert (1991) found that 29 of 31 women recovering from anorexia nervosa maintained their weight an average of 11 months when utilizing doses of fluoxetine between 20 and 80 mg daily. In a controlled study, Kaye et al. (1996) found that 63% of weight restored women with anorexia nervosa maintained a healthy body weight and a reduction in core eating disorder pathology for one year while taking fluoxetine. Only 16% of the participants taking a placebo maintained a healthy body weight. Thus, fluoxetine may be a promising agent in helping to prevent relapse in anorexia nervosa. More controlled studies are needed however, before firm conclusions can be drawn about the efficacy of fluoxetine with this population.

In sum, there is still little evidence for change in the early recommendations that pharmacotherapy has a very limited value with emaciated anorexia nervosa patients and should never be the sole treatment approach (Garfinkel & Garner, 1982). Occasionally patients may benefit from medication to deal with overwhelming anxiety, severe depression or intolerable gastric discomfort after meals, but this only applies to a small minority of patients (Andersen, 1985; Garfinkel & Garner, 1982; Garfinkel & Walsh, 1997).

5.23.9.2 Treatment Research on Bulimia Nervosa

In contrast to the lack of efficacy of medications in treating anorexia nervosa, there is some reason for optimism for the role of certain antidepressants in the treatment of bulimia nervosa (Garfinkel & Walsh, 1997; Raymond et al., 1994). The rationale for using antidepressants with bulimia nervosa was derived from several sources. First, as indicated earlier, Hudson and Pope (1988) argued that the efficacy of antidepressants in the treatment of bulimia nervosa suggests that it could be a variation of an affective illness. However, the failure to find any relationship between pretreatment levels of depression and response to medication does not support this view (Horne et al., 1988; Hughes, Wells, Cunningham, & Ilstruys, 1986; Walsh et al., 1988). Additionally, the dosage needed to be effective with bulimia nervosa is often substantially higher than the dosage used to treat mood disturbances (i.e., fluoxetine; FBNC, 1992).

Another more recent argument for pursuing antidepressants in treating bulimia nervosa is based on the hypothesis that dietary restraint may lead to lower levels of serotonin in the central nervous system. Binge eating may be driven by a need to increase brain serotonin (Walsh & Devlin, 1995). However, the merits of boosting serotonin with medication rather than with food is open to debate.

A review of the empirical literature on antidepressant treatment suggests that almost all antidepressants studied have been found to be superior to placebo in reducing binge frequency (Mitchell et al., 1993). Antidepressant therapy also leads to improvement in mood disturbances and reduces preoccupations with weight and shape. Only one controlled study, utilizing the antidepressant amitriptyline, failed to show a significant effect of the drug over placebo (Mitchell & Groat, 1984). Seven studies have been published that examine the efficacy of tricyclics such as imipramine and desipramine (Mitchell et al., 1993). Across these studies mean reduction in binge frequency was 69%. However, mean rate of abstinence from bulimic symptoms was only 24%. Moreover, the relatively high percentage of participants who relapsed while taking antidepressants is a concern (Pyle et al., 1990; Walsh, Hadigan, Devlin, Gladis, & Roose, 1991). For example, Walsh et al. (1991) found that 29% of participants who responded to desipramine during an eight-week trial relapsed during a four-month maintenance phase. Likewise, Pyle et al. (1990) assigned nine responders to a three-month trial of imipramine to either continue the drug treatment ($n = 3$) or to a placebo ($n = 6$). Five of the six participants in the placebo group relapsed and two of the three participants in the imipramine group relapsed. Of the tricyclics, desipramine is recommended as the first medication of choice given its suggested efficacy and minimal anticholineric effects.

There is growing evidence that third-generation antidepressants, selective serotonin reuptake inhibitors (SSRIs), can be effective in treating bulimia nervosa. A multisite collaborative study (FBNC, 1992) indicated that fluoxetine hydrocholride (Prozac) in daily dosages of 60 mg was superior to 20 mg dosages and probably should be used at least as an adjunct to psychotherapy in cases failing a course of adequate psychological treatment. Open studies have been conducted examining the efficacy of other SSRIs. Geretsegger, Greimel, Roed, and Hesselink (1995) conducted an open label study with ipsapirone and reported that 93% of the participants showed greater than a 50% reduction in weekly binges after four weeks of treatment. Mizes, Sloan, Ruderich, Freiheit, and Silverman (1996) found that sertraline yielded a significant reduction in bingeing and purging episodes among seven participants.

Studies that have compared the efficacy of antidepressant treatments to psychotherapeutic interventions have shown that psychotherapy is more effective than drug treatment alone and that participants who received combined drug and psychotherapy interventions may have slightly better outcomes (Agras et al., 1992; Leitenberg et al, 1994; Mitchell et al., 1990; Walsh et al., 1997). Agras et al. (1992) showed that a combined treatment of CBT and 24 weeks of treatment with desipramine yielded the highest rate of abstinence from bingeing at 32 weeks compared to CBT alone, desipramine alone, and CBT and desipramine treatment for 16 weeks. Likewise, Leitenberg et al. (1994) compared CBT alone, 20 weeks of desipramine treatment, and 20 weeks of combined treatments. There was a high (57%) dropout rate in the desipramine group, thus, the interpretation of the data is limited. However, the percentage of participants abstinent from vomiting at the six-month follow-up was substantially higher for those in the CBT group (57%) than for those in the desipramine group (0%) or in the combined treatment group (29%). Walsh et al. (1997) used a two-stage medication intervention for bulimia nervosa in which fluoxetine was employed if desipramine was either ineffective or poorly tolerated. This approach was compared to a combination of medication and two psychological treatments (cognitive-behavioral and psychodynamic-supportive). The results indicated that the two-stage medication intervention added modestly to the effects of the cognitive-behavioral treatment in reducing binge eating and depression. In addition, cognitive behavioral therapy plus medication was superior to medication alone; however, supportive psychotherapy plus medication was not more effective than medication alone.

MAOIs have been shown to be effective in reducing binge eating. Walsh et al. (1988) reported a 59% reduction in binge frequency in a controlled trial with an MAOI and Kennedy et al. (1988) reported a 22% reduction in binge frequency. However, side effects of MAOIs such as orthostatic hypotension, insomnia, and weight gain may be problematic. Additionally, dietary restrictions involving foods with a high concentration of tyramine or dopamine (aged cheese, beer) are necessary when taking MAOIs because high concentrations of tyramine or dopamine may cause a life threatening rapid increase in blood pressure. Placing people with bulimia nervosa on dietary restrictions is often counter to the therapeutic goals. Thus, it is generally recommended that MAOIs not be utilized as the first trial drug for this population (Kennedy et al., 1988; Walsh et al., 1988).

There have been a number of studies examining the utility of drugs other than antidepressants in the treatment of bulimia nervosa. Several studies of naltrexone, an opioid antagonist, have yielded mixed results. Mitchell, Davis, Goff, and Pyle (1986) reported a 23% decrease in binge size with naloxone. Alger, Schwalberg, Bigaouette, Michaleck, and Howard (1991) conducted a controlled trial with naltrexone and found that it significantly reduced the duration of bingeing episodes but was no better than placebo in reducing frequency of binges. In another controlled trial, naltrexone was no better than placebo in reducing symptoms of bulimia nervosa (Mitchell et al., 1989). Marrazzi, Bacon, Kinzie, and Luby (1995) reported on the results of a double-blind randomized crossover-design trial of naltrexone in treating participants with bulimia nervosa and anorexia nervosa. Out of the 19 participants, 18 showed a greater reduction in bingeing and purging while taking the naltrexone when compared to placebo. Given the mixed results of the above studies, the efficacy of treating bulimia nervosa and perhaps, anorexia nervosa with naltrexone warrants further investigation.

Mood stabilizing drugs such as lithium carbonate have been used in several trials, however, Garfinkel and Walsh (1997) concluded that "there is little evidence that most patients will benefit from their use" (p. 374). Fenfluramine has been studied with bulimia nervosa because of its effects in promoting satiety. An early study by Blouin et al. (1988) produced encouraging findings but a subsequent controlled trial showed no substantial clinical benefit of fenfluramine over placebo (Fahy, Eisler, & Russell, 1993).

5.23.10 FUTURE DIRECTIONS

A major premise in this chapter has been that eating disorders are multidetermined and heterogeneous syndromes resulting from the interplay of biological, psychological, familial, and sociocultural predisposing factors. In this sense, they are probably best understood as final common pathways that appear to have different psychological points of entry. Within this overall context, this chapter has selectively reviewed diagnostic issues, major etiological formulations, and associated psychopathology applied to eating disorders.

From research to date it may be concluded that there has been as much resistance to dispelling the "uniformity myth" applied to eating disorders as has been the case with disorders with a longer or more visible history in the psychological nomenclature. However, research since the mid-1980s has yielded notable advancements in refining the criteria for eating-disordered subgroups and in providing more rigorous research examining psychopathology or psychological topologies associated with diagnostic subtypes. An important direction for future research will be the clearer specification of the relative contribution of particular biological, psychological, and interpersonal predisposing features considered relevant to eating disorders. It is to be hoped that the extraordinary clinical and research interest in personality disorders, depression, sexual abuse, and addictive behaviors as related to eating disorders will continue to lead to improved understanding. Further research is clearly needed to determine the precise nature and the significance of the observed associations. If past research to date is any indication of future findings, the within-diagnostic-group variability will continue to be as noteworthy as the between-group differences.

It is now evident that certain patients respond relatively quickly to brief interventions, in contrast to others who require more intensive and protracted treatments. Perhaps the most significant goal for future research will be the identification of traits, personality features, or background factors that predict differential response to treatment. Even better would be a taxonomy yielding an accurate match between patient characteristics and treatment type.

Advances in research on psychopathology and treatment efficacy warrant genuine optimism with regard to bulimia nervosa. Less is known about personality and response to treatment for anorexia nervosa because of the relative absence of controlled treatment research with this eating disorder. It is hoped that controlled treatment research will assume a high priority, and that the results will generate the same level of progress as is now evident with bulimia nervosa.

5.24.1 INTRODUCTION

Sleep or rest appears to be a basic need of every organism. Despite many years of sleep research, many of the fundamental questions such as the function of sleep have only been partially resolved or replaced by more specific questions, such as the function of rapid eye movement (REM) sleep or the influence of daytime naps on functioning.

In the attempt to unveil the function of sleep, research efforts have focused mainly on the effects of sleep deprivation on the individual's mental and physiological functioning. It has been shown that significant and prolonged sleep deprivation can lead to serious cognitive and behavioral deficits and can eventually cause medical complications and even death in extreme cases. The effects of partial sleep deprivation, which is closer to the phenomenology of sleep disorders, have been less striking, but in general the literature suggests that the partially sleep-deprived individual may pay a significant price in behavioral, cognitive, and medical terms (e.g., Babkoff, Caspy, Mikulincer, & Sing, 1991; Bonnet, 1985). Despite the fact that extensive research has been conducted on the effects of sleep deprivation in animals and in adults, only limited research efforts have been focused on children. These studies have demonstrated relationships between sleep disorders and learning and behavior problems in children and adolescents (see Alvarez, Dahlitz, Vignau, & Parkes, 1992; Dahl, 1996; Kahn, Mozin, Rebuffat, Sottiaux, & Muller, 1989; Quine, 1992; Thorpy, Korman, Spielman, & Glovinsky, 1988).

From a clinical perspective, sleep is a very sensitive barometer to the medical and mental well-being of the individual. The most prominent manifestation of the close relationships between sleep and psychopathology and medical disorders is the presence of sleep difficulties or sleep-related complaints as symptoms or even as major diagnostic features of many psychiatric and medical disorders.

The close ties between sleep disorders and psychopathology are best manifested in professional diagnostic systems such as the *DSM-IV* (American Psychiatric Association, 1994). In addition to more than 50 manual pages dedicated to sleep disorders, sleep-related problems are often included in the symptoms or diagnostic criteria of other major affective and anxiety disorders (see Table 1). In addition, it has been demonstrated repeatedly that sleep is very sensitive to psychosocial stressors. Extensive research has documented the vulnerability of the sleep–wake system to various experimental and natural stressors, ranging from sleeping in an unfamiliar setting (i.e., the sleep laboratory) to serious traumatic life events (see Sadeh, 1996, for a recent review).

Table 1 Sleep-related difficulties associated with *DSM-IV* diagnoses of the American Psychiatric Association, 1994.

Mood disorders

Major depressive episode: insomnia or hypersomnia, fatigue and loss of energy, irritable mood in children

Manic episode: decreased need for sleep, and distractibility

These symptoms are manifested in less severe forms of affective disorders.

Anxiety disorders

Generalized anxiety disorder: sleep disturbances (difficulty in falling or staying asleep, or restless unsatisfying sleep), being easily fatigued, irritability and restlessness

Post-traumatic stress disorder: difficulty in falling or staying asleep, difficulty concentrating, hypervigilance, recurrent distressing dreams (nightmares)

Separation anxiety disorder: persistent reluctance or refusal to go to sleep without being near a major attachment object, repeated nightmares involving the theme of separation

Source: American Psychiatric Association (1994).

Disrupted sleep has also been associated with difficult temperament in early childhood (e.g., Carey, 1974; Sadeh, Lavie, & Scher, 1994; Zuckerman, Stevenson, & Baily, 1987). It has also been shown that older children who suffer from sleep problems are more likely to exhibit other behavior problems (Gass & Strauch, 1984; Jenkins, Bax, & Hart, 1980; Richman, Stevenson, & Graham, 1982).

Most of the studies demonstrating strong links between sleep and behavior problems or psychopathology are correlative in nature and therefore preclude a better understanding of the cause-and-effect nature of these relationships (see Dahl, 1996; Sadeh, Hayden, McGuire, Sachs, & Civita, 1994; Sadeh et al., 1995c). This important issue is evident in the case of attention deficit and hyperactivity disorder (ADHD). A number 882044of studies have documented higher rates of sleep problems in children diagnosed with ADHD compared to normal children (see Dahl, 1996). These studies included subjective and objective measures that supported the notion that the sleep of ADHD children is significantly more disturbed or shorter (e.g., Tirosh, Sadeh, Munvez, & Lavie, 1993). Traditionally, clinicians and parents tended to interpret this finding intuitively by attributing the sleep problem to the fact that the child is running in "turbo" mode or is hyperalert, and therefore, cannot stop and initiate sleep or is still hyperactive during sleep. Research supports the competing hypothesis that sleep deprivation in children may lead to behaviors or symptoms associated with ADHD such as inattention, difficulties in concentration and sustaining attention, impulsiveness, and increased activity level (Anders, Carskadon, Dement, & Harvey, 1978; Navelet, Anders, & Guilleminault, 1976). There have been some descriptions of clinical cases of children diagnosed with ADHD that suffered from a major sleep disorder, where treating the underlying sleep disorder led to disappearance of the ADHD symptoms (Dahl, 1996; Dahl, Pelham, & Wierson, 1991).

Sleep disruptions have also been associated with various medical disorders. For example, asthma is considered to be one of the most common illnesses during childhood, affecting 5–15% of children (e.g., Strachan, Anderson, Limb, O'Neill, & Wells, 1994). Asthma is a disorder of the respiratory system which tends to become more dysfunctional during sleep. Indeed, sleep difficulties are very often associated with asthma during childhood, with a survey in 1995 reporting that as many as 61% of asthmatic children suffer from sleep difficulties (Madge et al., 1995).

5.24.2 SLEEP DISORDERS IN CHILDREN

Sleep disorders cover a wide range of phenomena associated with the multiple sleep–wake systems related to the specific mechanisms responsible for consolidated and refreshing sleep, inhibition of behavior during sleep or sleep–wake transitions, control of breathing during sleep, and the timing of sleep ("the biological clock").

A number of diagnostic systems exist for sleep disorders (e.g., American Psychiatric Association, 1994; Diagnostic Classification Steering Committee, 1990; World Health Organization, 1992). These systems vary in their emphasis on phenomenology, etiology, and medical or psychosocial factors. The following description will be based on the *DSM-IV* (American Psychiatric Association, 1994). Due to space limitations, many issues will be only partially addressed or not addressed at all. For additional information, the reader is referred to professional books on children's sleep disorders (Ferber & Kryger, 1995; Guileminault, 1987; Sheldon, Spire, & Levy, 1992).

The first diagnostic distinction used by *DSM-IV* with regard to sleep disorders is between the dyssomnias and the parasomnias. Dysomnias refers to the disorders of initiating or maintaining sleep and to those related to excessive sleepiness. These disorders include: primary insomnia, primary hypersomnia, narcolepsy, breathing-related sleep disorder, and circadian rhythm 1651828sleep disorder. 1472630Parasomnias are disorders manifested in unique behaviors or physiologic phenomena occurring during sleep or sleep–wake transitions.

5.24.2.1 Phenomenology31890000

The clinical presentation of various sleep disorders often changes as the child matures, and the involvement of parents as primary observers and reporters changes accordingly.

5.24.2.1.1 Primary insomnia

Primary insomnia is related to disorders in initiating and maintaining sleep (DIMS). This diagnosis covers the most common sleep complaints during childhood and include problems such as difficulty going to bed, difficulty falling asleep, and multiple and/or prolonged night-wakings. This category is equivalent to the *ICD-10* classification of "nonorganic insomnia" (World Health Organization, 1992). The clinical picture is related to the developmental status of the child, as are the source of the referral, the etiology, and the clinical interventions.

During infancy and early childhood, the most common complaints (usually of the parents) are related to the child's incapacity to "sleep through the night" which is manifested in difficulties such as falling asleep without parental involvement, multiple and prolonged night-wakings during which the child usually signals (by crying or calling), and requires parental intervention to resume sleep. In most cases, the child does not exhibit strong manifestations of distress during the day and compensates during daytime napping for the sleepless nights. The parents are often exhausted by their child's sleep difficulties, and in many cases they show signs of distress and tension that may lead to difficulties in their daily functioning and their relationship with the child.

As children mature, during the preschool and school ages, the clinical features of insomnia undergo significant changes. The dominance of night-wakings and difficulties in resuming sleep following nocturnal awakening during early childhood is replaced by sleep onset difficulties, bed refusal, fears, and bedtime struggles. When fears are involved the child often seeks the proximity of the parents during the night and may end up cosleeping with the parents. The child is usually able to address these fears and the subsequent reluctance to go to sleep or difficulties to resume sleep after night-waking. Older children and adolescents may lie in bed for prolonged periods unable to fall asleep or resume sleep. In many cases, the parents are unaware, or are only partially aware of the problem, because the child no longer seeks their attention.

Parental and cultural attitudes, and the different lifestyle of the family, may have a significant influence on whether a specific set of problems or behaviors are considered a sleep problem. For instance, parent–child cosleeping is considered a normal and acceptable practice in many cultures and by many parents. In these families, cosleeping is a habitual sleeping arrangement that meet the needs of the parents and their culture. However, in western societies, cosleeping is usually an unfavored practice that generally represents an attempt to solve a child's sleep problem.

5.24.2.1.2 *Primary hypersomnia*

Excessive sleepiness is usually manifested by very extended sleep periods and an unusual pressure to sleep during the daytime. This relatively rare cluster of disorders is not fully understood and may be the result of different neurologic or physiologic origins. One recurrent form of the disorder, the Kleine–Levin syndrome has, in addition to the excessive sleep episodes, other clinical manifestations that may be confused with psychiatric disorders. These behaviors include indiscriminate and inappropriate sexual behavior, compulsive overeating, and in some individuals other symptoms such as depression, confusion, irritability, and hallucinations. The Kleine–Levin syndrome is relatively rare and more prevalent in males (approximately 3:1 ratio). The age at onset is usually middle or late puberty but no prevalence estimates exist for children or adolescents.

ICD-10 specifies nonorganic hypersomnia as a separate classification that is usually associated with other mental disorders such as affective disorders (World Health Organization, 1992).

5.24.2.1.3 *Narcolepsy*

Unintentional sleep episodes are common phenomena in sleepy or sleep-deprived individuals. However, in narcolepsy, sleep attacks unexpectedly, regardless of the situation and in combination with cataplexy (sudden loss of muscular tone in response to emotional stimuli), hypnogogic hallucination, and loss of muscle tone (paralysis). The disorder is very serious and highly disruptive to normal life. Narcolepsy is associated with excessive daytime sleepiness, difficulty waking in the morning, and in many cases with hyperactivity (Guilleminault, 1987).

5.24.2.1.4 *Breathing-related sleep disorder*

The maintenance of continuous breathing during wakefulness as well as during sleep is a crucial function of the central nervous system (CNS) and other peripheral systems. During sleep, the breathing system is more vulnerable and more likely to fail than during wakefulness. Failures in breathing during sleep lead to arousals, fragmented, and nonrefreshing sleep. Clinical complaints in children may include excessive sleepiness and low level of arousal, or other symptoms associated with fatigue in children such as irritability and hyperactivity. Observers (usually the parents) may report loud snoring and long episodes of breathing pauses during sleep terminated by a loud and active breathing effort. Most affected children (as well as adults) are unaware of their snoring, breathing difficulties, and sleep fragmentation. Sometimes the child may even be considered a "good sleeper," since they readily go to bed and sleep through the night and for an extended duration. In addition, children with obstructive sleep apnea may experience breathing problems during wakefulness, may be more susceptible to complications in diseases associated with upper airways blockage, and present features such as swallowing difficulties and poor speech articulation.

Breathing-related sleep disorders are further subdivided into obstructive, central, and mixed sleep apnea and other nonapnea disorders. A discussion of these subcategories is beyond the scope of this chapter.

5.24.2.1.5 Circadian rhythm sleep disorder

The evolution of sleep–wake rhythms that favors the dark hours for nocturnal sleep occurs during the first few months of life. “Sleeping through the night” is the expression used to describe this maturational milestone. However, this association between the light–dark and the sleep–wake cycles cannot be taken for granted. Circadian rhythm sleep disorders (CRSD) relate to all the deviations or the incongruity between these basic rhythms. Children with CRSD may experience difficulties falling asleep at normal, age-appropriate evening hours and waking up in the morning, but would be “good sleepers” given the opportunity to go to sleep at very late hours and wake-up later in the morning (delayed sleep phase type, DSPT; Weitzman et al., 1981). Other children may experience the opposite problem, the advanced sleep phase, manifested in difficulty staying awake until normal evening bedtime hours with a tendency to wake up for the day at a very early morning hour. Other possible manifestations include the irregular sleep–wake patterns and the non-24-hour sleep–wake patterns that describe deviations from a regular sleep–wake schedule. These disorders, if not attributed to organic factors, fall under the *ICD-10* category of nonorganic disorder of the sleep–wake schedule (World Health Organization, 1992).

Children and adolescents with CRSD may experience serious problems when forced to adapt to normal social schedules such as early school hours. When they encounter serious difficulties waking up in the morning for the school day they are often considered unmotivated and face disciplinary actions from their parents and school authorities who fail to appreciate the potential biological origin of their problem.

Irregular and non-24-hour sleep–wake patterns are often reported in blind children and in children with pervasive developmental disorders or other neurobehavioral disorders (Lapierre & Dumont, 1995; Okawa et al., 1987; Sadeh, Klitzke, Anders, & Acebo, 1995; Tzischinsky, Skene, Epstein, & Lavie, 1991)

In addition to the above disorders of the biological clock, some externally induced schedule disorders exist. These disorders include the rhythm disturbances associated with the jet-lag phenomenon or with other forced shifts of the sleep–wake schedule. These disorders are usually transient and disappear with time after the normal sleep-wake schedule is reinstated.

5.24.2.1.6 Nightmare disorder

This is the first representative of the heterogeneous group of the parasomnias. The main feature of the nightmare disorder is the repeated occurrence of terrifying dreams that result in the child’s awakening. Following the nightmare, the child often exhibits high levels of anxiety that may lead to refusal to go to bed, or to stay alone in the dark. Young children usually respond to their parents’ attempts to soothe them but may insist on parental proximity for prolonged periods.

Verbal children may report the content of the dream and it may relate to their daily lives or their normal anxieties such as getting lost or being separated from their parents. Children may also report scary dreams about monsters, evil animals, or other creations of their imagination, or those they were exposed to while watching TV or movies. Other prevalent nightmares are those related to loss of control (e.g., free fall from different places) and a variety of threats of self-injury and death (e.g., drowning). It has been reported that many children refrain from sharing these private negative experiences with their parents and therefore parents may be unaware what their child is experiencing (Terr, 1987). A similar category exists in *ICD-10* (World Health Organization, 1992).

5.24.2.1.7 Sleep terror disorder

The sleep terror disorder is characterized by the repeated occurrence of abrupt awakenings from sleep with a scream or cry that conveys the sense that the child is terrorized. Usually the child continues to yell, cry, and fight during these episodes and is difficult to awaken or comfort. In many cases the child, even with open eyes, does not appear to recognize their parents and may struggle with them as they try to calm the child who also presents signs of autonomic arousal such as tachicardia, rapid breathing, sweating, pupils dilation, increased muscle tone, and flushing of the skin. The child does not remember these events the following morning. If awakened during the episode, the child looks confused and disoriented. Usually the child does not reach full awareness and returns to sleep following the episode. The night terror events commonly last between one and 10 minutes but can be longer if the child is not awakened by their parents. A similar category exists in *ICD-10* (World Health Organization, 1992).

5.24.2.1.8 Sleepwalking disorder

Sleepwalking episodes are common in childhood. The phenomenon may have different manifestations, but typically, the child gets out of bed in the middle of the night and starts wandering around the house. The child may look confused and disoriented but is capable of finding their way around and sometimes performs quite complex activities. Parents may find the child asleep on a different bed in a different room the next morning or may notice the episode while it is occurring and redirect the child to bed to resume normal sleep. Many different behaviors are seen during nightwalking episodes. These behaviors include eating, using the bathroom (sometimes urinating in inappropriate places), talking, or fearful running around. Usually the child has no recollection (or only vague memory) of the sleepwalking episode the following morning. Since these behaviors are highly counterintuitive many parents tend to be alarmed by these events and seek professional help. A similar category exists in *ICD-10* (World Health Organization, 1992).

5.24.2.1.9 Other parasomnias

There are some other unusual behavior patterns that have been associated with sleep and are considered parasomnias. These parasomnias include: REM sleep behavior disorder (activities and behaviors occurring during REM sleep and are associated with vivid dream recall), sleep paralysis (inability to move during sleep–wake transitions), and rhythmical movement disorders, periodic leg movements in sleep, and bruxism (tooth grinding).

5.24.2.2 Diagnostic Features

The diagnostic process of sleep disorders in children should include the following considerations:

(i) the disordered aspect of sleep (e.g., sleep schedule, sleep quality, or related behaviors);

(ii) the primary origin of the disorder (physiologic and organic vs. psychosocial);

(iii) the psychophysiological effects of the disorder (e.g., deteriorated daytime functioning);

(iv) the psychosocial effects of the disorder (e.g., disrupts parent–child relationships);

(v) Other potential external causes (e.g., substance abuse, another medical or psychiatric disorder).

All of the diagnostic systems are based on the principle that a medical origin for the disorder should be excluded (including comorbidity with another major mental disorder) before a psychosocial diagnosis is made. The origins of a number of specific disorders such as circadian rhythm sleep disorders and the parasomnias are not fully understood and therefore such a distinction is not always justified.

5.24.2.2.1 Primary insomnia

The *DSM-IV* diagnostic criteria for primary insomnia are as follows: (i) the predominant complaint is difficulty initiating or maintaining sleep, or nonrestorative sleep, for at least one month; (ii) the sleep disturbance (or associated daytime fatigue) causes clinically significant distress or impairment in social, occupational, or other important areas of functioning; (iii) the sleep disturbance does not occur exclusively during the course of another primary sleep disorder; (iv) the disturbance does not occur exclusively during the course of another mental disorder; and (v) the disturbance is not due to the direct physiological effects of a substance or a general medical condition.

In addition to these standard diagnostic criteria, a differential diagnosis of primary insomnia should exclude the diagnosis of CRSD. Furthermore, difficulties falling asleep at a certain age-appropriate hour may result from the child's anxieties, fears, and other psychosocial factors that would justify the diagnosis of primary insomnia. However, if these difficulties result from the child's biological tendency to fall asleep at a late hour (assuming the child is not experiencing any difficulties), then the child is probably suffering from sleep-phase delay and therefore a diagnosis of CRSD would be warranted.

5.24.2.2.2 Primary hypersomnia

Excessive sleepiness during the day is a normal experience explained by many factors including chronic insufficient sleep or sleep deprivation, transient effects such as jet-lag, and identified sleep disorders such as insomnia or breathing-related disturbances. All these factors must be excluded before considering primary hypersomnia as a diagnosis.

The major *DSM-IV* diagnostic criteria for primary hypersomnia is the predominant complaint of excessive sleepiness for at least one month (or less if recurrent) as evidenced by either prolonged sleep episodes or daytime sleep episodes that occur almost daily. All of the other criteria are similar to those of primary insomnia, with the exception that primary insomnia as well as other primary sleep, mental, and medical disorders must be excluded before reaching a primary hypersomnia diagnosis.

Primary hypersomnia as defined by *DSM-IV* tends to be very rare in general, and particularly so, in children. Most of these disturbances have a late age of onset, usually appearing during adolescence or adulthood. The Kleine–Levin syndrome is distinguished by prolonged sleep episodes and by the clinical manifestation of inappropriate sexual and aggressive behaviors described earlier.

5.24.2.2.3 Narcolepsy

The *DSM-IV* criteria for narcolepsy are as follows: (i) irresistible attacks of sleep that occur daily over at least three months; (ii) the presence of cataplexy (sudden loss of muscle tone, most often in association with intense emotion) and/or recurrent intrusions of elements of REM sleep into the transition between sleep and wakefulness, as manifested by either hypnopompic or hypnagogic hallucinations or sleep paralysis at the beginning or end of sleep episodes; and (iii) the disturbance is not due to the direct physiologic effects or a substance or another general medical condition.

5.24.2.2.4 Breathing-related sleep disorder

The *DSM-IV* uses only two criteria for breathing-related sleep disorder (BRSD): (i) sleep disruption due to a sleep-related breathing problem; and (ii) the disturbance is not better explained by another mental disorder or by direct physiological effects of a substance. Since the child is usually unaware of having disturbed sleep in BRSD and the parents may also be unaware of the disorder, the first diagnostic signs are very often signs of fatigue, sleepiness and other manifestations of difficulties in arousal level. The full diagnosis of BRSD requires a complete laboratory assessment including monitoring of the breathing system during sleep and a medical examination that includes assessment of the airway (nasal airflow, tonsillar size, mandibular, and facial abnormalities). These assessment procedures can verify the existence of a BRSD, its severity, its subtype (e.g., central vs. obstructive apnea), and the appropriate intervention.

5.24.2.2.5 Circadian rhythm sleep disorder

Like many other species in nature, the human mind is programmed to be alert during daytime hours and to rest or sleep during night time hours. The circadian clock is a very powerful mechanism underlying our behavior and functioning. It includes a nonspecific general clock that controls our rest–activity cycle and multiple clocks that affect various distinct domains of human behavior such as different cognitive functions (Monk, 1994; Montagner, De Roquefeuil, & Djakovic, 1992). The initial step in diagnosing CRSD is the identification of a persistent sleep problem that results from a mismatch between the individual's own circadian sleep-wake pattern and the environmentally appropriate sleep–wake schedule. In addition, *DSM-IV* requires the following requirements: clinically significant stress or a functional impairment and the exclusion of another sleep or mental disorder and any substance effects.

As indicated earlier the major diagnostic issue is differentiating between primary insomnia and CRSD (see Section 5.24.5).

5.24.2.2.6 The parasomnias

Isolated and infrequent episodes of the parasomnias are very common in children. Most forms of these episodes are prevalent during early and middle childhood and become uncommon during adolescence. Therefore, it is difficult to draw the line when these episodes should be considered a disorder. The basic guideline is that a diagnosis of a disorder should be made whenever the phenomenon becomes very frequent, involves violent or dangerous behaviors, or results in significant functional impairment. In addition, if the phenomenon persists from childhood to adolescence it is more likely to warrant a diagnosis.

The main diagnostic criteria for nightmare disorder is repeated awakenings from sleep with recall of terrifying dreams that usually involve threats to survival, security, and self-esteem. Very young children may not be able to produce verbal recall but usually appear oriented and communicative. On awakening from these dreams the child rapidly becomes oriented and alert and usually responds well to parental comfort.

Differential diagnosis from sleep terror disorder is based on these features of dream recall, orientation, and interactive responsiveness which are quite distinguishable from the disorientation and relative unresponsiveness that characterized the sleep terror. In addition, sleep terror disorder is associated with severe autonomic arousal response. Differentiation between sleep terror disorder and epilepsy or REM sleep behavior disorder is based on electroencephalogram (EEG) records and specific stereotyped behaviors.

Sleepwalking disorder is characterized by repeated episodes in which the child rises from bed during sleep and walks about relatively unresponsive to others. It is difficult to awaken the child, and once awake the child is usually amnesic regarding the episode. Another feature is that the child's normal behavior is usually restored shortly after a full awakening from the episode.

Another parasomnia that does not fall under specific *DSM-IV* diagnostic category is that of rhythmical movement disorder. This disorder refers to the very common phenomena of self-soothing behaviors performed by the child during sleep-wake transitions. These behaviors, such as body rocking, head rolling, and banging, are common in young children (more than 50%) and are usually considered normal behavior. But when the phenomenon becomes disruptive or is perceived to be dangerous (e.g., an infant that bangs its head fiercely against the wall), parents often become alarmed and seek professional help.

5.24.2.3 Prevalence

The review of the literature on issues pertaining to prevalence and incidence of sleep problems in children is quite disappointing. The number of solid and systematic studies in this field is very small. In most fields, these studies do not usually involve consensus clinical guidelines or diagnostic criteria, and therefore it is difficult to assess the prevalence rates of these disorders using any systematic diagnostic system. However, the existing surveys provide some sense as to which phenomena are more prevalent than the others and their peak age of onset and time course.

5.24.2.3.1 Primary insomnia

The prevalence of primary insomnia and its etiology appears to change systematically during development and therefore close attention should be given to developmental issues when assessing children presenting with insomnia.

Moore and Ucko (1957) defined a night-waking problem when the child awakened and cried at least once between midnight and 5 a.m. on at least four of seven nights, for at least four consecutive weeks. Using this definition and relying on maternal reports, they reported that at three months of age 70% of the infants "slept" through the night, whereas 83% of the six month olds and 90% of the nine month olds "slept" through the night. Richman (1981) defined sleep problem in one-year-old infants as either regular sleep onset fussing periods lasting more than 30 min, or night-waking episodes that required parental intervention occurring at least four nights a week. Other surveys using parental reports indicated that 20–30% of the children suffer from these problems during the first three years (e.g., Adair, Bauchner, Philipp, Levenson, & Zuckerman, 1991; Beltramini & Herzig, 1983; Jenkins, et al. 1980; Johnson, 1991; Richman, 1981; Scher et al., 1995; Zuckerman et al., 1987). Research based on objective sleep measures derived from methods like time-lapse video and actigraphy (activity based monitoring) suggests that night wakings are more prevalent than reported by parents (Anders; 1979; Paret, 1983; Sadeh, Lavie, Scher, Tirosh, & Epstein, 1991). For instance, it was found that nonreferred normal young children (9–24 months of age) woke-up twice a night on average in comparison to an average of more than four night-wakings in referred "sleep-disturbed" infants (Sadeh et al., 1991). Most of these infants resumed their sleep without fussing or requiring help and therefore their parents were not even aware of their night-wakings.

In school-age children the prevalence of primary insomnia appears to drop to 1–5% (Gass & Strauch, 1984; Richman et al., 1982). However, there are indications that these problems are underestimated because older children are less likely to alert their parents to their sleep problems (Anders et al., 1978). Kahn et al. (1989) surveyed predadolescents (aged 8–10 years) using parental reports. A prevalence of 43% for a variety of sleep difficulties was reported by the parents. "Poor sleep," a rough equivalent of primary insomnia, was reported in 14% of the children.

In adolescence, chronic or severe sleep difficulties have been self-reported by 11–33.4% of the youth (Bearpark & Michie, 1987; Kirmil-Gray, Eagleston, Gibson, & Thorensen, 1984; Morrison, McGee, & Stanton, 1992; Price, Coates, Thoresen, & Grinstead, 1978). Since these surveys did not use detailed criteria to identify the exact nature of the problems (e.g., difficulty falling asleep due to primary insomnia vs. delayed sleep phase), it is difficult to provide good estimates of primary insomnia in this age group.

5.24.2.3.2 Primary hypersomnia and narcolepsy

Primary hypersomnia and narcolepsy are relatively scarce in young children and tend to appear in adolescence or adulthood. It is estimated that the prevalence of narcolepsy in the general population ranges between 0.04% and 0.09% (Dement, Carskadon, & Ley, 1973).

Narcolepsy is usually diagnosed in late adolescence or in adulthood. In a study of 400 narcoleptic patients, Yoss and Daly (1960) reported that only 4% were younger than 15 years when their diagnosis was made. Retrospective studies suggest that early signs of the disorder may appear earlier in many children. Challamel et al. (1994) reported on the basis of aggregated studies of 235 adult patients that 34% of the patients presented their first narcoleptic symptoms before they were 15 years old and 16% before they were 10 years old. There are, however, claims that professionals often fail to diagnose narclopsy and therefore the disorder is either underdiagnosed or its diagnosis is seriously delayed (Baird, 1987).

5.24.2.3.3 Breathing-related sleep disorder

The prevalence of BRSD in children is unknown. It is certainly not a rare disorder, but data on prevalence in the general population is lacking.

5.24.2.3.4 Circadian rhythm sleep disorder

The prevalence of CRSD in children has not been established but the awareness of these disorders is growing rapidly. During adolescence when there is a normal tendency to delay the sleep phase the prevalence is estimated as high as 7% for delayed sleep phase type.

5.24.2.3.5 The parasomnias

It is estimated that 10–50% of children aged three to five years have nightmares severe enough to alarm their parents. Since nightmares are such a prevalent experience (at least on a periodic or sporadic basis), it is difficult to estimate how many of these children warrant a diagnosis of nightmare disorder. The prevalence of nightmares in older children has not been established although there are indications that the phenomenon decreases significantly as children grow beyond the preschool years.

The prevalence of night terror disorder is estimated between 1% and 6% in children (Beltramini & Hertzig, 1983; Gass & Strauch, 1984; Kales et al., 1980a; Klackenberg, 1987). It is also estimated that the prevalence of this disorder decreases with age.

Sleepwalking appears to be a prevalent phenomenon during childhood. One study reported that 15% of 5–12-year-olds have had at least one episode. An incidence of 10% for at least two episodes during a year period prior to the study was reported for 3–11-year-old Swiss children (Gass & Strauch, 1984). The peak age for sleepwalking in this study was 10. In a longitudinal study of 212 children studied between six and 16 years of age, the incidence of sleepwalking was 40%. But when the frequency of the episodes was examined, only 2–3% of the children had experienced at least one episode a month. The prevalence rates peaked at ages 11–12 years (Klackenberg, 1987).

5.24.2.4 Etiology

Sleep as a biobehavioral phenomenon is affected by multiple maturational, physiological, environmental and psychosocial factors. Different sleep disorders vary in their loading on medical and psychosocial factors. Primary insomnia is by definition the disorder that is most likely to originate or be maintained by psychosocial and environmental factors. Primary hypersomia and BRSD are more heavily influenced by medical factors. On the other hand, CRSD and the parasomnias are loaded by a complex matrix of physiological and psychosocial factors that are difficult to untangle.

5.24.2.4.1 Primary insomnia

The timing, duration, and structure of sleep change dramatically during the first year of life. On average, newborns spend close to 18 h in sleep each day. Their sleep is multiphasic and consists of five to six sleep episodes spread throughout the daytime and night-time hours. Significant individual differences in sleep duration exist already during the first few days of life (Sadeh, Dark, & Vohr, 1996). While some newborns sleep close to 22 h a day, others spend only 7–8 h in sleep. In a rapid maturational process during the first year of life, most infants significantly reduce sleep duration and their sleep progressively becomes more consolidated and concentrated during the night. These developmental changes are crucial for the understanding of early childhood insomnia because most of the problems seen in infants and young children could be viewed as a developmental delay. Most infants develop consolidated sleep, sometimes described as "sleeping through the night," toward the end of the first year. This significant shift is very sensitive and can be complicated and compromised by many factors.

Another significant process that occurs during the first year of life is the transition from the parents as the major soothing agents of the infant to a growing self-regulatory self-soothing capacity. This transition is manifested in the parents decreased involvement around bedtime and the child's growing ability to fall asleep without parental presence. Close relationships exist between parental involvement in the soothing processes and the child's difficulty falling asleep and night-waking problems (Adair et al., 1991; Johnson, 1991; Van Tassel, 1985). Many intervention studies show significant improvement or resolution of children's night-waking and difficulty falling asleep when parents are encouraged to withdraw from their active involvement around bedtime (see Section 5.24.4). These findings suggest that the etiology of many of these problems is heavily influenced by parent–child bedtime interactions that either reward the child for activities that are incompatible with self-soothing and consolidated sleep patterns or prevent the pressure to develop more appropriate ones.

Other psychosocial factors such as parental and in particular, maternal psychopathology have also been associated with increased likelihood of sleep problems in the child (e.g., Benoit, Zeanah, Boucher, & Minde, 1992; Guedeney & Kreisler, 1987; Richman, 1981; Scott & Richards, 1990; Seifer, Sameroff, Dickstein, Hayden & Schiller, 1996; Van Tassel, 1985; Zuckerman et al., 1987). In general this literature suggests that maternal depression, sense of incompetence, separation difficulties, and insecure attachment may contribute to or exacerbate sleep problems in early childhood. It has been suggested that these parental attitudes, personality and psychodynamic factors affect sleep through direct bedtime interactions (Sadeh & Anders, 1993).

Trauma, stress, and anxiety are the underlying cause of many forms of primary insomnia (Sadeh, 1996). It has been documented in numerous studies on stress and trauma in children that sleep difficulties are among the most common nonspecific responses to such conditions (see Sadeh, 1996, for a review). In many cases it is possible to link the onset of the disorder, as an immediate or delayed response, to stressful or anxiety provoking events. Often it is difficult to trace back the association and a disorder that originated from stress continues to be maintained by other intervening factors.

In older children, anxieties and fears are probably the most common cause of primary insomnia but the theme of these anxieties may change according to phase-specific issues. For instance, a 3-year-old child may develop nighttime fears and sleep onset difficulties in response to a transition to a new daycare program, while an 11-year-old child may develop anxieties and sleep onset difficulties in response to a growing sexual awareness and anxieties related to masturbation that are likely to rise when the child is alone in bed.

From a different angle, primary insomnia in children has been associated with the child's personality and psychopathology. Close links between sleep problems and "difficult temperament" and other behavior problems have been documented (see Section 5.24.1). The causal links are difficult to interpret but undoubtedly children with behavior or temperament problems, whatever the source of these difficulties, are more likely to develop sleep disorders. A similar picture exists in adolescence. Sleep problems have been associated with depression, anxiety, and related negative self-perceptions (Dahl, 1996; Kirmil-Gray et al., 1984; Marks & Monroe, 1976; Price et al., 1978).

Beyond the psychosocial and developmental factor in the etiology of primary insomnia, it is important to note that some common physiological factors may underlie the clinical picture. For instance, a number of medical and physiological factors may be involved in the etiology of night-waking problems in infants and young children. Among those identified factors are milk intolerance (Kahn et al., 1989), esophageal reflux (Kahn et al., 1991), atopic eczema (Reid & Lewis-Jones, 1995), and colic.

5.24.2.4.2 Primary hypersomnia and narcolepsy

Little is known about this cluster of relatively rare disturbances. The etiology of these disorders is usually attributed to neurological and hormonal processes. Genetic and hormonal influences have been identified in disorders such as Kleine–Levin and narcolepsy. Some of these processes have been associated with pubertal changes, thus explaining their onset and other phenomena such as the links, in some cases, between the clinical manifestations and the menstrual cycle. The origin of these disorders is organic in nature although most of the underlying neurophysiological mechanisms are still unknown. Insufficient or dysregulated sleep tends to exacerbate the clinical manifestations of these disorders.

5.24.2.4.3 Breathing-related sleep disorder

The most common cause for BRSD in children is airway obstruction due to anatomical and neurological complications. Enlarged tonsils and adenoids are among the prevalent reasons for upper airway blockage. Central sleep apnea is caused by CNS failure to control the breathing process. Full understanding of the various mechanisms involved in this family of disorders is still lacking, however.

5.24.2.4.4 *Circadian rhythm sleep disorder*

The understanding of the etiology of CRSD has significantly increased since the mid-1970s. Some of the mechanisms involved in mediating between the light–dark cycle and the sleep–wake rhythm have been identified and systematically studied. This new knowledge includes the specific role of the hormone melatonin, which is secreted from the pineal body during darkness, in transferring the external light–dark information into other brain centers controlling the sleep–wake cycle. It is now more clearly understood that the 24-h sleep–wake rhythm requires constant light–dark information and when such information is blocked (e.g., by experimental measures or blindness), the sleep–wake cycle loses its stable organization. This explains why reports on specific CRSD disorders, such as free-running or disorganized sleep–wake rhythms, have mostly been associated with blind adults and children, and more specifically with their different melatonin secretion patterns (e.g., Lewy & Newsome, 1983; Tzischinsky et al., 1991). Another group that has been associated with CRSD is children who suffer from "brain-damage" or psychoneurological, developmental disorders. It is assumed that these children either have dysfunctional neurological systems that fail to control the circadian clock or have difficulties interpreting the environmental cues that are essential for controlling the circadian system.

Delayed sleep phase has mostly been associated with adolescence as adolescents seem to have a natural tendency to delay sleep onset and insufficient sleep (Carskadon & Dement, 1987). It has been suggested that this delay tendency is not only due to the psychosocial influences of adolescence but also associated with pubertal changes (Carskadon, Viera, & Acebo, 1993).

5.24.2.4.5 *The parasomnias*

Little is known about the etiology of the parasomnias. A number of constitutional or predisposing genetic, developmental, and psychological factors have been suggested as well as factors associated with sleep structure. Anxiety, stress, and insufficient sleep are among the factors that may contribute to or exacerbate these phenomena.

5.24.2.5 Developmental Course

The issue of the persistency and continuity of sleep problems in early childhood is important since the common belief shared by many professionals and parents is that children outgrow these problems and therefore early interventions are not critical. Despite the fact that maturational processes seem to resolve the sleep difficulties in many young children, a number of studies have shown that these problems tend to be very persistent (Kateria, Swanson, & Trevarthin, 1987; Richman et al., 1982; Salzarulo & Chevalier, 1983; Zukerman et al., 1987). For instance, when infants identified as sleep-disturbed at 8 months of age were revisited when they were three years old, 41% of them still suffered from sleep problems (Zuckerman et al.). These studies indicate that many sleep-disturbed children continue to suffer from sleep problems for prolonged periods although the characteristics of their problem may change significantly. Some retrospective studies with adult insomnia patients report that a large proportion of these patients suffered from sleep problems from early childhood, suggesting that these problems are likely to turn into chronic disorders if not treated (Hauri & Olmstead, 1980).

The course of hypersomnia, BRSD, and the parasomnias is very specific to the source of the disorder and the interventions involved. As described earlier, some disorders (the Kleine–Levin syndrome, narcolepsy) tend to appear (or to be diagnosed) in adolescence. In contrast, the parasomnias tend to appear in early childhood and disappear as the child matures, usually prior to or during adolescence.

5.24.3 CONCEPTUALIZATION AND CLINICAL FORMULATION

The assessment and diagnosis of sleep disorders in children should be based on two components: (i) the assessment of sleep schedule, sleep duration, and sleep quality; and (ii) the assessment of daytime functioning and signs of fatigue, sleepiness, and other arousal disorders.

One unique feature of sleep disorders that separates it from many other psychosocial and biobehavioral disorders is that in addition to subjective or parental reports, sleep can be directly measured and quantified by objective measures that have been established by extensive research efforts. However, in clinical practice and clinical research the assessment of common sleep disorders of childhood is still mostly based on subjective reports. This section reviews some of the available objective measurement tools for clinical assessment of sleep disorders. Some of these assessment tools (such as polysomnographic (PSG) studies) are often necessary to identify organic or medical sources for the disorders and are therefore crucial for correct diagnosis and treatment. In many cases, it is also crucial to exclude major psychiatric or developmental disorders when diagnosing sleep disorders.

5.24.3.1 Multimodal Assessment

Since sleep–wake regulation plays such a major role in the arena of emotional regulation and psychopathology (Dahl, 1996), it is imperative for any clinical diagnostic procedure within the context of medical or behavioral disorders to include screening questions regarding the possible existence of sleep or alertness problems. This screening investigation should include questions regarding sleep schedule, sleep quality, known or suspected sleep disorders, and questions regarding daytime sleepiness and fatigue (Dahl & Carskadon, 1995; Ferber, 1995; Sadeh & Anders, 1993).

The assessment of sleep disorders involves a systematic intake interview and, in many cases, medical examination and laboratory or ambulatory monitoring of sleep–wake patterns. In addition, when excessive sleepiness is suspected, it is important to objectively evaluate the level of sleepiness of the child.

5.24.3.1.1 Initial information

Parents or other caregivers are generally the best source of information regarding the child's present sleep problem, its history and etiology, and the associated psychosocial factors. If the child is old enough they may be able to describe the difficulties, particularly when emotional and psychosocial factors play an important role. The preliminary information for screening and evaluating sleep disorders includes the child's sleep patterns (schedule, quantity, and quality), sleep history, bedtime rituals, and other psychosocial factors. In many cases, it is recommended that the parents and/or the child be asked to complete a daily sleep log for one week to provide more detailed information regarding specific issues that are of interest to the clinician and to serve as a baseline assessment for later treatment progress evaluation. It is also important to understand what kind of interventions or efforts have been made already to solve the problem (i.e., self- or professionally-driven attempts) (Dahl & Carskadon, 1995; Ferber, 1995; Sadeh & Anders, 1993).

In assessing primary insomnia, primary hypersomnia, and the parasomnias in infants and children it is particularly important to evaluate the psychosocial, individual, and family contexts. The assessment should include efforts to identify specific stressors in the child and family's life, given the important role that stress plays in these disorders (Sadeh, 1996).

When there is a suspected or potential physical or medical source for the disorder, a medical examination is required as part of the initial assessment.

5.24.3.1.2 Assessment of sleep

Clinicians interested in sleep disorders have the advantage of being able to measure and quantify the clinical problem objectively in addition to receiving subjective reports of the child or the parents. With infants and children the parents are usually the reporters; however, their ability to report is limited. Parents are mostly aware of their child's sleep problem if the child signals (cries and requires intervention) during the night or, in the case of older children, if they communicate their problem directly to their parents (Sadeh, 1996; Sadeh & Anders, 1993). It has been shown that parents are relatively good reporters of their child sleep–wake schedule, but when it comes to sleep quality (i.e., number or duration of night-wakings), their reports are less accurate and might be adversely affected by various motivational and situational factors (Sadeh, 1996; Sadeh et al., 1991).

The traditional objective and comprehensive method to assess sleep is PSG (e.g. Anders, Emde, & Parmelee, 1971). This method is usually based on a laboratory study (although ambulatory studies have started to gain in popularity in recent years) for a single night. PSG provides information regarding the EEG, the electro-oculogram (eye movements), the electromyogram (muscle tone), and respiratory patterns during sleep. These data enable assessment of sleep structure, sleep stages, and specific disturbances during sleep such as those related to disordered breathing.

A number of ambulatory methods have been developed to assess sleep in the child's natural home environment. These methods include direct observations (Thoman, 1975), time-lapse video recording (Anders & Sostek, 1976), pressure-sensitive mattress recording of motility and respiration (Thoman & Whitney, 1989), and actigraphy–activity monitoring with a wrist-watch like device that has already been adopted for clinical practice (Sadeh, 1994; Sadeh et al., 1991, 1995a). See Table 2 for a description of the advantages and shortcomings of each method.

Table 2 Assessment tools for diagnosis and treatment follow-up in sleep disorders.

Method	*Description*	*Advantages*	*Limitations*
Polysomnography	Laboratory or ambulatory multiple-channel physiologic recording that requires wiring electrodes, post-testing interpretation (Anders et al., 1971)	Provides the most elaborate data. Crucial for diagnosing organic causes for sleep disorders	Expensive, disrupts natural sleep settings, and causes stress. Usually limited to one night
Videosomnography	Time-lapse video enables the monitoring of child's sleep patterns at home (Anders & Sostek, 1976)	Provides information about sleep onset, sleep–wake states, night-wakings, and parental interventions	Requires transportation to the home, and a postmonitoring observer scoring
Sensitive mattress	A system based on a pressure sensitive mattress installed in the child's bed (e.g., Thoman & Whitney, 1989)	Provides useful information about sleep–wake states and respiratory patterns	Requires home installation and a complex postmonitoring analysis
Direct observation	This method is based on trained observers who observe the infant and record his or her sleep–wake states on an ongoing basis. In addition a sensor pad and a strip chart recorder provide respiration data that facilitate state differentiation (e.g., Thoman, 1975)	Provides valuable information on sleep–wake and to some extent on sleep states in infants ("quiet" vs. "active" sleep). Provides information on respiration patterns	May disrupt normal home-setting. Very demanding task for the observers and requires complex postmonitoring analysis. Has only been used with infants
Actigraphy	Actigraphy is based on a small computerized activity monitor attached to the child's wrist or ankle. The activity data is automatically translated to sleep–wake measures that have been validated against polysomnography (Sadeh et al., 1995a)	Enables 24 h continuous nonintrusive measurement of sleep–wake and activity patterns. Cost-effective. Provides information on sleep schedule, night-wakings, and sleep quality	Some artifact may result from the fact that the only channel measured is activity. Sleep disturbances seen in the activity data are difficult to interpret without complementary information
Sleep diary	Parents or child complete a sleep diary that includes bedtimes, sleep onset time, number and timing of night-wakings and other sleep-related events and disruptions (e.g., Douglas & Richman, 1984)	Easy and inexpensive to administer. Provides additional information regarding relevant events associated with sleep (e.g., how the parents intervene)	Limited by the subjective knowledge of the parents or the child. May be biased by a variety of motivational issues. Parents and children may lose interest with prolonged administration
Sleep questionnaires	Parents or child complete a general sleep questionnaire characterizing their sleep problems (e.g., "child wakes up regularly every night")	Easy to administer. Provides general information on sleep difficulties	The subjective components may play a major role since the questions are not anchored to specific nights as in the daily logs

5.24.3.1.3 Assessment of excessive sleepiness

As described earlier, fatigue and excessive sleepiness may have different manifestations in children. The primary sign of sleepiness is a tendency or a growing pressure to sleep. Other signs in infants and children include irritability, fussiness, hyperactivity, affective dysregulation, difficulties in attention, and concentration (Dahl, 1996). Many of these signs may be observed directly in the school or the clinical setting or reported by the parents.

The multiple sleep latency test (MSLT) was designed to measure and quantify the pressure to fall asleep in children and adults (Carskadon & Dement, 1982). The basic procedure is to ask the subject to lie in bed with eyes closed and to try to fall asleep. Individuals who fall asleep rapidly (e.g., within 5 minutes) are considered very sleepy. Higher sleep latencies are interpreted as increased alertness. This procedure is repeated a few times during daytime hours. Norms and clinical criteria have been established.

5.24.3.2 Treatment Formulation

Treatment strategy is heavily based on the diagnosis and the clinical interpretation of applicable intervention avenues. For most clinical sleep disorders, pharmacological treatments are available, although the pervasive belief is that whenever possible the use of sleep-related drugs should be avoided, particularly with children. Potent psychosocial treatments are available for many sleep disturbances and they should be considered the treatment of choice.

Although Section 5.24.5 presents psychosocial and medical–pharmacological treatments separately, it is important to remember that this is not the recommended approach, rather, an integrated approach is usually called for. Even when medical treatment is required, motivational and psychological factors of the child and the parents play a major role in their response to treatment and therefore should be evaluated and addressed in the course of treatment.

5.24.4 TREATMENT

This section discusses the different approaches to treatment in children's and adolescents' sleep disorders. Due to the heterogeneous nature and the wide variety of sleep disorders, there are multiple psychosocial and medical therapeutic approaches. The following section reflects an attempt to review this wide range of interventions with a special focus on the psychosocial approaches.

5.24.4.1 Psychosocial Treatments

The psychosocial treatments of sleep disorders in infants and children constitute a relatively well-documented domain of multiple behavioral and psychodynamic approaches. This is particularly true for infants and young children and less so for older children and adolescents. Most of the emphasis is on primary insomnia which is the disorder that responds best to these interventions.

5.24.4.1.1 Primary insomnia

The recommended psychological treatment should include both behavioral components aimed at changing the sleep habits of the child and a psychodynamic component enabling the working-through of psychodynamic issues related to sleep difficulties (whenever such issues exist). The main issues in such a brief and focused psychological treatment are usually related to separation, soothing capacities, and limit setting. Therefore, in addition to the benefits of solving the specific sleep disorder, the brief psychological treatment might serve as a vehicle for the parents and child to acquire skills and competencies that may be useful in broader contexts (e.g., self-soothing, limit-setting).

The central hypothesis that underlies most behavioral interventions in early childhood is that sleep problems are the result of habitual, learned parent–child interactional patterns (Sadeh & Anders, 1993). Sadeh & Anders (1993) suggest that one of the key factors in the evolution of sleep problems in childhood is related to soothing skills that are acquired by children during development. The lack of these self-soothing skills is manifested in the case of a 18-month-old boy who cannot fall asleep without being rocked or breast-fed by his mother or by the 10-year-old girl who refuses to sleep in her own bed separated from her parents because of fears associated with sleep, dreaming, or darkness. An additional assumption is that sleep difficulties may be associated with sleep-competitive activities, that have been maintained by a variety of positive and negative reinforcers (Bootzin, 1977; Bootzin & Nicassio, 1978), such as parental reactions that perpetuate the sleep difficulties (Blampied & France, 1993). Hence, the target of the different modes of the behavioral treatment is to break these associations by teaching the child to fall asleep and to maintain sleep with minimal interaction with the parents.

Since the capacity for "sleeping through the night" is acquired by most infants by six months of age, most parents and clinicians prefer to wait for the maturational process to occur during this period. Despite this general attitude, it has been shown that an improvement in sleep patterns may be achieved by behavioral intervention with breast-fed infants as young as eight weeks old (Pinilla & Birch, 1993), or even by prevention programs based on educating expecting parents (in delivery classes) how to help their children develop healthy and mature sleep habits (Wolfson, Lacks, & Futterman, 1992).

According to the "behavioral extinction" approach, parents are instructed to stop attending to the child during the night. They are instructed to ignore the child's crying and protests until the child falls asleep due to exhaustion and lack of reinforcers (Sadeh & Anders, 1993). However, the extinction approach is difficult to implement for most parents since there is usually a postextinction response burst, an increase in the frequency and intensity of the behavior that is likely to accompany the introduction of extinction (Lawton, France, & Blampied, 1991; Rickert & Johnson, 1988). This treatment is difficult for many parents who experience such behavior as abandonment on their part. Therefore, more gradual and less aversive variants of the extinction technique have been recommended.

In the gradual extinction approach, the parental response to the child during falling asleep or night-waking are suspended for constant (Douglas & Richman, 1984) or increasing intervals of time (Ferber, 1995), and parents are advised to decrease their proximity to and involvement with the child during the night. For example, a parent may initially stop rocking the child to sleep, and instead remain close to the child's bed for a while until the child falls asleep. In the next step, the parent would leave the child's bedroom once the child has been put to bed (Sadeh & Anders, 1993).

Another alternative aimed at to make the extinction less aversive for both child and parents is using a combination treatment of sedative medication for the child and extinction (France, Blampied, & Wilkinson, 1991).

The stimulus control therapy attempts to break the association between the sleep environment and wakefulness by teaching the child not to engage in sleep "incompatible" behavior in the bedroom, and to establish the bed and bedroom as cues for sleep (e.g., to be in the bedroom only when drowsy or asleep) (Bootzin & Perlis, 1992).

Another way to break the rewarding association among night-waking, crying, and parental intervention is that of "scheduled awakenings." According to this approach the parents awaken the child prior to the time of the expected spontaneous awakening (McGarr & Hovel, 1980).

Parental cosleeping with the child has been used as an intervention method. According to this method, one parent sleeps in the child's bedroom for a one-week period without having any other interactions with the child throughout the night. This method is based on the assumption that in many cases infant sleep problems are related to the child's separation anxiety. The presence of the parent in the child's room is expected to reassure the child and enable consolidated sleep (Sadeh, 1994).

The methods described above are usually implemented within a standard clinical setup including clinical sessions with a therapist. However, some programs have used only written information and guidelines to the parents as the sole intervention. Written manuals containing instructions for parents without therapist support were found as highly effective in reducing waking during the night as the "conventional" format. The improvement was more gradual than the improvement in the sleep program with therapist involvement, but there was no difference in the final achievements of both groups (Seymour, Brock, During, & Pole, 1989). Adoption of behavioral principles into a group therapy format was not found to be effective (Messer, Lauder, & Humphrey, 1994).

Many studies demonstrate the efficacy of behavioral interventions in treating sleep problems, particularly during early childhood. Generally, the reported success rate range has been between 73% and 90% (e.g., Adair, Zuckerman, Bauchner, Philipp, & Levenson, 1992; Jones & Verduyn, 1983; Richman, Douglas, Hunt, Landsdown, & Levere, 1985; Roberts, 1993; Sadeh, 1994). Moreover, it has been found that a brief behavioral intervention program focused on helping families manage children with sleep disturbances could be generalized to improving daytime mother–child interactions (Minde, Faucon, & Falkner, 1994).

High success rates have been reported for a variety of extinction strategies (e.g., Adair et al., 1992; Adams & Rickert, 1989; Durand & Mindell, 1990; France & Hudson, 1990; Jones & Verduyn, 1983; Pritchard & Appelton, 1988; Richman et al., 1985; Rickert & Johnson, 1988; Sadeh, 1994).

Most of the reports have documented dramatic improvement within a one-week period. The use of extinction is reportedly accompanied by reduction in parental anxiety, and improvement in parental self-esteem, depression, marital satisfaction, and sense of control following extinction-based treatments of sleep disturbance. In addition, an improvement in infant sense of security has also been documented (France et al., 1991). These findings could be used to reassure parents who fear that such a strategy may harm their child. The stimulus control therapy was found to be effective, though its efficacy was measured in combination with other therapeutic components (Weissbluth, 1982). The scheduled awakening strategy proved difficult for parents to follow though it was found to be effective in reducing the number of night-wakings (e.g., McGarr & Hovel, 1980; Ricket & Johnson, 1988; Weissbluth, 1982).

All of the above reported efficacy studies are based on parental reports with their obvious limitations with one exception that has used both parental reports and actigraphic monitoring (Sadeh, 1994). This study documented two processes that occur during these interventions: (i) the infant's sleep becomes more consolidated and less fragmented; and (ii) the children acquire the capacity to soothe themselves back to sleep without parental interventions.

Psychodynamic approaches have also been implemented in treating early childhood primary insomnia. Psychodynamically oriented approaches have been used in order to understand and interpret the meaning of the child's sleep behavior in the context of the child–parent relationship (Daws, 1989). Since many sleep problems in children reflect parent–child interactions, parental anxieties, and psychopathology, these issues become the focus of psychodynamic treatment. The efficacy of the psychodynamic approach is yet to be established empirically, however, we believe that family and psychodynamic issues should be addressed in most cases to facilitate the efficacy of behavioral interventions.

As the child matures, the characteristics of the insomnia progressively resemble those seen at older ages and the insomniac adolescent gradually resembles the insomniac young adult and similar approaches found to be effective with adults can be adopted (Ferber, 1995). These methods include improving sleep hygiene, normalizing sleep schedules, stimulus control, sleep restriction training, biofeedback, cognitive therapy, and dynamic psychotherapy (Ferber, 1995; Morin et al., 1994).

Since little research has been conducted with adolescent subjects, efficacy of the different approaches is based on studies with adult subjects. The findings from different studies and reviews indicate that nonpharmacological interventions produce reliable and durable changes in sleep patterns of patients with chronic insomnia (e.g., Bootzin & Perlis, 1992; Morin et al., 1994). For instance, Morin et al. conducted a meta-analysis of nonpharmacological interventions for insomnia to examine the efficacy of the different treatment approaches. They found that psychological intervention produced a reliable change in sleep latency and in time awake after sleep onset.

5.24.4.1.2 *Primary hypersomnia and narcolepsy*

In addition to the pharmacological treatments, psychosocial interventions in hypersomnia and narcolepsy focus on two main issues: (i) regulating the sleep–wake schedule and extending sleep to reduce sleepiness (e.g., scheduling daily naps, maintaining strict and regular sleep–wake schedule; and (ii) consulting the child, the parents, and the school system in an effort to optimize the child's social and school adjustment.

Daytime sleep schedules have been found to be effective in reducing somnolence during the day (Billiard, 1976; Roehrs et al., 1986; Rogers & Aldrich, 1993) and in improving cognitive functioning (Mullington & Broughton, 1993). In addition to the difficulties to function due to the excessive sleepiness, narcoleptic children may suffer adjustment problems due to the unique form of their syndrome. Adult narcoleptic patients have been described as depressed and prone to adjustment disorders, anxiety, personality disorders, and alcohol dependency. There are also some indications that most adult narcoleptic patients benefit from psychotherapy and support groups (Alaia, 1992; Zarcone, 1973). The efficacy of such interventions with children and adolescents has not been established, however.

5.24.4.1.3 *Breathing-related sleep disorder*

The treatment of these disorders is primarily medical. Psychological work with the child and family is often focused on compliance with some of the medical interventions.

5.24.4.1.4 *Circadian rhythm sleep disorder*

Readjustment of the circadian system requires small, gradual, and consistent changes in bedtime and wake-up time, and requires one to two weeks of stability to realign all the components of the system (Dahl, 1992). This gradual change could be achieved by the combined effect of chronotherapy and light therapy.

The traditionally accepted treatment for delayed sleep phase is chronotherapy (Czeisler et al., 1981). Chronotherapy is a behavioral technique in which bedtime is systematically delayed or advanced, following the child's natural biological tendency (Ferber, 1995). Czeisler et al. reported that chronotherapy was effective in advancing sleep onset and wake-times with no reduction in sleep efficiency in five adult patients. Research focused on treatment in infants and adolescents has yet to be conducted.

In dealing with the adolescent age group, treatment must include behavioral contracts with specifically delineated rules, rewards, consequences, and a measure of monitoring components (Dahl, 1992). The behavioral contract should specify the time of going to sleep and awakening, avoidance of napping during the day, and the amount and timing of exposure to bright light. Parents and child should agree upon the reinforcements for keeping the program. The reinforcements should be given on a weekly basis during follow-up meetings with the therapist. The importance of keeping to the new schedule as strictly as possible, including holidays and weekends, must be emphasized and explained to the child and the parents. It is only after the schedule has been stabilized that there may be a place to negotiate "exceptions" for special occasions (e.g., trips, parties).

The treatment of delayed sleep phase syndrome was found to be effective in adolescents who were cooperative and were not suffering from depression, but was not effective in adolescents who expressed a refusal to go to school (Ferber & Boyle, 1983). In other studies, it was demonstrated that patients who had delayed phase syndrome and significant psychopathology (e.g., depression) responded poorly to treatment (Billiard, Verge, Touchon, Carlander, & Besset, 1993; Lahmeyer & Lilie, 1987). Therefore, it seems that whenever the circadian rhythm disorder is complicated by additional psychopathology, the success of treatment depends on the success of additional psychotherapy and psychiatric treatments.

When there are motivational factors that help perpetuate the problem (e.g., social or academic problems that the child is trying to avoid by staying away from school when tired, or special incentives for the child to stay up late), individual and family psychotherapy is recommended in addition to chronotherapy and light therapy.

5.24.4.1.5 Nightmares, sleep terror, sleepwalking, and other parasomnias

Two components should be considered in the approach to treating specific parasomnias. The first component is that of management aimed at providing protection and safety for the child. This is the most important consideration in coping with sleepwalking or night-terror episodes (Kales et al., 1980b; Kales, Soldatos, & Kales, 1987). The second component is additional symptomatic treatment in those cases where the arousals are dangerous or disruptive to the child or the family and no obvious precipitant can be identified (Rosen, Mahowald, & Ferber, 1995). When attacks are very frequent, if they persist beyond the age they would normally cease, if they start beyond that age (Stores, 1990), or if they follow a traumatic event (Rosen et al., 1995; Stores, 1990), protection is not enough and there might be a need for additional treatment.

Regarding the management of night terrors and sleepwalking, the recommendations are very practical. It is advisable to remove everything from the bedroom (and house) that could be hazardous. If possible, it is recommended that the bedroom be located on the ground floor of the house. It is important to lock the windows and cover the panes with heavy drapes (Keefauver & Guilleminault, 1995). In addition, it is recommended that sleep deprivation or other circumstances that might cause the child excessive sleep be avoided (Driver & Shapiro, 1993) and that the sleep–wake schedule be made regular (Rosen et al., 1995).

It is important to assure both the parents and the child that the problem is temporary, and that it is neither "abnormal" nor bearing significant consequences for the future (Mahowald & Rosen, 1990). It is also important to recommend that the parents do not discuss the episodes with the child the following day, since such discussion might be stressful for the child (who usually does not remember anything) and it may inadvertently reinforce the behavior. Furthermore, during the night, parents should resist trying to awaken and comfort the child. Waking the child may increase disturbance (Stores, 1990). The most appropriate response is to help the child to settle down when the acute episode subsides or if the child awakens when it ends. In cases in which night terrors occur at a regular and predicted time, it is possible to wake the child before each episode, keep them awake for few minutes, and thus break the cycle of night terror (Stores, 1990).

Another treatment approach is based on relaxation mental imagery. This form of treatment allows the child to utilize self-regulation techniques to control the previously uncontrolled night-time behaviors (Mahowald & Rosen, 1990). This method has been described as effective in treating parasomnias (Driver & Shapiro, 1993; Pesikoff & Davis, 1971).

When treating nightmares there is a special need to address potential sources for the fears (e.g., horror films) and to remove them (Dahl, 1992), simultaneously providing support and comfort to the child (Driver & Shapiro, 1993).

Psychotherapy is indicated with children and in families where significant psychopathology is present.

5.24.4.2 Pharmacological and Other Medical Treatments

Medical interventions play a significant role in treating many sleep disorders. While in some disorders, drugs and other medical interventions are the only available treatment, in other disorders they are too readily used when they should not be considered the treatment of choice.

5.24.4.2.1 Primary insomnia

Most experts in the field believe that medication is not a recommended treatment for insomnia in children. However, in practice high rates of medication use have been reported for infants and children.

The most common hypnotics that have been used for treating insomniac children are niaprazine (Nopron R) and trimeprazine tartrate (Vallergan Forte R) (Navelet, 1996). Sedatives such as chloral hydrate (Adler, 1990), benzodiazepines, and sedatives containing cough medicine have also been used by clinicians (Chavin & Tinson, 1980; Dahl, 1992; Werry & Carlielle, 1983).

Generally, it has been found that in the short-run sleep problems improve with the use of sedatives. However, most of the studies have not differentiated between different types of sleep disorders or ages of the children, and possess methodological deficiencies. For example, Russo, Vymut, and Gurauraj-Allen (1976) found dipheramine HCl to be effective in decreasing sleep latency time and reducing the number of awakenings in children aged 2–12 years who had a variety of sleep difficulties. Besana, Fiocchi, DeBartolomies, Magno, and Donati (1984) found niaprazine to be effective in the treatment of sleep disorders in children aged 2–13 years who had difficulties with onset and maintaining of sleep due to different emotional and medical conditions. However, both studies did not differentiate between different age groups or different sleep disorders. In a different clinical setting, Simonoff and Stores (1987) found tromerazine to be an effective treatment in reducing night-waking. However, their sample consisted of children with severe psychopathology and therefore does not represent the majority of infants with sleep difficulties.

Despite short-term improvement in insomnia as the result of sedative use, studies have shown little or no long-term benefit (Chavin & Tinson, 1980; Jones & Verduyn, 1983; Richman, 1986; Richman et al., 1985; Seymour, 1987). In addition, side effects of using sedatives in children include tolerance effects, withdrawal effects, and the fact that children who are not able to self-comfort behaviorally will often fight sleep despite the sedatives. This could result in increased levels of activity and awareness of the child when he or she is medicated (Dahl, 1992). Moreover, the problem may recur when the medication is stopped.

The use of medication is usually not indicated for insomnia in adolescents unless it is to treat a specific disorder that is related to insomnia. Since the insomnias that seem most likely to occur in adolescents are primarily associated with either psychiatric problems or with a circadian rhythm disorder, it seems important to make a careful diagnosis, and, in cases of psychiatric disorders such as anxiety or depression, the medication should be appropriate in treating both the sleep problem and the affective problem (i.e., by sedatives that provide an anxiolytic or depressant effect the next day; see Nicholson, 1994). When choosing to use sedatives, it is advisable to prescribe relatively small doses that enable the preservation of normal sleep architecture both during ingestion and after withdrawal.

Sleep-inducing medications may have adverse effects such as impaired performance the following day and anterograde amnesia, rebound insomnia when treatment is stopped, dependence, and developed tolerance.

5.24.4.2.2 Primary hypersomnia and narcolepsy

There is little empirical data in the younger narcoleptic population to guide treatment decisions (Dahl, 1992). Hence, the treatment of narcolepsy and cataplexy in children reflects clinical experience with older adult patients (Lawrence & Billiard, 1995).

The goal of the pharmacological treatment is to control the narcoleptic symptoms and to allow the patient full participation in daily activities. Pharmacological treatment usually includes: REM-suppressant medication such as trycyclic antidepressants and clomipramine, desmethylimipramine, or other 5HT2 reuptake inhibitors aimed at dealing with cataplexy and hypnogogic hallucinations, and stimulant medication such as pemoline and methylphenidate, or amphetamines aimed at dealing with daytime sleepiness (Parkes, 1994). The effectiveness of these pharmacological treatments in increasing alertness of narcoleptic patients has been demonstrated in a number of studies (Guillerminault, 1993; Rogers & Aldrich, 1993). However, since narcolepsy is a long-lasting illness, it is important to take into account issues related to tolerance, addiction, and adverse side effects.

It is important to remember that despite medication, most adult narcoleptic patients experience narcoleptic symptoms, especially somnolence, which is very disruptive to functioning during the day (Scumacher, Merritt, & Cohen, 1993). Further research should be conducted to evaluate the efficacy of pharmacological treatments of narcolepsy in children.

5.24.4.2.3 Breathing-related sleep disorder

Optional medical treatments for obstructive sleep apnea syndrome (OSAS) include surgical, mechanical therapy, and medical–pharmacological treatment. The surgical approach includes adenotonsillectomy and tracheostomy that are often used in treating sleep apnea in children and adults. Adenotonsillectom, removing tonsils and adenoids, is a solution for enlarged tonsils and adenoids that have been found to cause obstruction (Stores, 1990; Stradling, Thomas, Warely, Williams, & Feeland, 1990). Tracheostomy is a surgical intervention aiming at enlarging the breathing passway itself by introducing a canula into it. Tracheostomy is indicated for children with severe and/or complicated OSAS in whom other treatment approaches are either not possible or unsuccessful.

Since there are potentially serious complications involved in these surgical procedures, they are recommended only in serious cases (Carrol & Louglin, 1995; Powell; Guilleminault, & Riley, 1994). There is little scientific information and no consensus or guidelines for surgical treatment of childhood OSAS (Carrol & Louglin, 1995). Hence, further research concerning efficacy of this treatment strategy is required.

Nasally applied continuous airway pressure (CPAP) has become the major nonsurgical, long-term form of treatment used in obstructive sleep apnea and it is currently the treatment of choice. The method is based on providing intermittent positive pressure through a nose mask to overcome obstructions and hypoventilation syndromes (Sullivan & Grunstein, 1994). When CPAP treatment is initiated there is an immediate reduction in daytime somnolence. This has been demonstrated using the multiple sleep latency test (Lamphere, Roehrs, & Wittig, 1989). Serious complications of CPAP appear to be rare. Nasal congestion is a side effect of CPAP therapy that can be pharmacologically or, in very rare cases, surgically treated.

CPAP is effective in reducing the severity of obstructive sleep apnea, but it does not lead to a permanent cure (Marcus et al., 1995). CPAP treatment for OSAS was found to be effective in more than 85% of the pediatric patients. Objective measures such as MSLT, before and after one year of treatment, have confirmed its efficacy in adults, indicating that after a year of CPAP treatment sleepiness as measured by the MSLT was significantly raised (Sforza & Lugaresi, 1995).

In contrast with the reported efficacy of the CPAP treatment, the use of medication to treat sleep apnea has been disappointing (Strollo & Rogers, 1996). Nasal decongestants and topical steroids can be used as a short-term solution in cases of OSAS in children.

5.24.4.2.4 Circadian rhythm sleep disorder

Since the architecture of sleep in CRSD has no abnormalities, and because the patients usually have no difficulties with sleep onset given the opportunity to sleep at a less commonly accepted time of day, there is no indication for drug therapy in this disorder.

A relatively new approach to the treatment of sleep problems is the use of melatonin for regulating sleep. Melatonin plays an important role in the induction of sleep in the human organism. The secretion of melatonin is controlled by an endogenous rhythm-generating system in the brain which is synchronized by the light-dark cycle, so that melatonin levels are high during dark hours and low during light hours.

Exogenous melatonin has been found useful in the treatment of sleep disorders in adults (Dahlitz et al., 1991; McFarlane, Cleghorn, Brown, & Streiner, 1991); however, some studies have shown that the results are not maintained when treatment is terminated (Alvarez et al., 1992; Dahlitz et al.). There are relatively few studies examining melatonin therapy for sleep disorder in children.

Melatonin treatment has been found to be effective in treating highly disabled children with severe sleep disorders that have resisted conventional treatment (Jan, Espezel, & Appelton, 1994). In addition, melatonin has been found to be effective in treating blind retarded children with a problematic sleep–wake cycle (Lapierre & Dumont, 1995). However, concerns regarding the safety of using melatonin in prepubertal children have been raised due to the links between melatonin and sexual maturation.

Since the circadian cycle, and hence the sleep–wake cycle, may be shortened or lengthened by exposure to bright light (Regestein & Monk, 1995), early morning exposure to bright light and activity can be an important adjunct to maintaining an early schedule (Dahl, 1992). Exposure to bright light has been shown to be effective in treating circadian rhythm disorders in adult patients (e.g., Lack & Wright, 1993; Lewy, Singer, & Sack, 1985). Guilleminault, McCann, Quera-Salva, and Cetel (1993) reported a positive response in five of 14 mentally retarded and neurologically damaged children with severe sleep disorders.

5.24.4.2.5 *Nightmares, sleep terror, sleepwalking, and other parasomnias*

Drug treatment may be considered if night terrors or sleepwalking occur very frequently, or if the problem interferes with the child participating in normal social interactions. The common drugs for treating parasomnias are diazepam, imipramine, benzodiazepines, and tricyclic antidepressants. For night terrors, both diazepam and imipramine have been shown to be effective. Diazepam is considered the drug of choice because it is associated with fewer side effects (McDaniel, 1987). Benzodiazepines and tricyclic antidepressants have been shown to be useful (Fisher, Kahn, Edwards, & Davis, 1973; Guilleminault, 1994; Kavey, Whyte, Resor, & Gidro-Frank, 1987). Low doses of a benzodiazepine may also be effective (Fisher et al., 1973; Pesikoff & Davis, 1971), but there is a high rate of relapse particularly during times of stress (Driver & Shapiro, 1993).

Combining pharmacological and psychological treatment may be effective: drugs could be used for treating acute current difficulties, and different therapeutic tools could be used for long-term treatment, thus avoiding tolerance and adverse side effects.

5.24.5 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

This chapter raises many areas of insufficient knowledge and research efforts. Information on diagnosis, prevalence, time course, and interventions is lacking for many specific sleep disorders. Many of the definitions of the disorders are too vague and rely heavily on subjective interpretations of the child, parents, and clinicians. Despite the fact that a number of objective assessment tools have been established, they have yet to be adopted for clinical research and practice.

Clinical sleep research has mostly focused on two age periods: infancy and adulthood. There is a significant gap in clinical knowledge on children during school years and the adolescent period. For instance, there are clinical assumptions that school children and adolescents can benefit from relaxation training and other behavioral methods that have demonstrated efficacy with adults; however, this efficacy has not been established for children.

Another area with limited information pertains to the maturational-developmental processes of the sleep–wake system beyond early childhood. Longitudinal research is needed to assess the continuity of sleep problems across the life span effects of early disturbances of the sleep–wake system on other behavioral and neuropsychological systems.

There is a growing body of research indicating that: (i) sleep disturbances are very common in early childhood; (ii) sleep problems in early childhood are persistent; and (iii) brief and focused interventions are effective in treating most of the common sleep problems. This knowledge should be translated to clinical practice by shifting the focus to prevention and early detection and intervention. The study of Wolfson et al. (1992) is a good example of a prevention program and its potential efficacy.

The strong links between sleep problems and psychopathology require special attention. Future experimental and clinical studies should focus on assessing the role of sleep disorders and sleep deprivation in the evolution of psychopathology in children.

We believe that in the near future the current trend of adopting a multidimensional approach in diagnosing and treating sleep disorders will become the prevailing standard of practice. This multidimensional approach will include: (i) objective and subjective assessment of sleep; (ii) assessment of psychosocial factors including psychopathology and stress; (iii) combining behavioral or medical treatment with psychosocial interventions aimed at psychodynamic and family issues associated with the disorder; and (iv) assessing the efficacy of interventions by subjective and objective measures.

5.24.6 SUMMARY

This chapter raises a number of clinical and empirical issues that are fundamental to the diagnosis and treatment of children's sleep disorders.

(i) Sleep disorders are very prevalent during infancy, childhood, and adolescence. Since many studies have not used standard criteria to define specific sleep disorders, and some disorders have been studied mostly in clinical settings, the prevalence of many specific disorders in the general population has not been well established.

(ii) Despite the fact that objective measures of specific disorders like night-waking problems have been established, they have not been incorporated into clinical research and practice which is still heavily based on subjective reports.

(iii) The diagnostic criteria for many specific disorders are still relatively vague with no empirical consensus. Therefore, in clinical research it is difficult to compare studies and in many cases to even identify the specific disorders under investigation.

(iv) Sleep disorders, daytime behavior, and psychopathology are highly inter-related. Screening for sleep problems should be included in any clinical assessment with children. Specific attention should be given to daytime sleepiness and paradoxical signs of fatigue.

(v) When signs of sleepiness and fatigue exist with no "simple" explanation, such as insufficient sleep, a full evaluation is needed, including identification of medical disorders such as breathing-related sleep disorders by means of a full polysomnographic study.

(vi) When a sleep disorder exists in the context of known psychopathology one should not assume that the psychopathology is the cause of the sleep problem. The sleep problem should be thoroughly assessed and treated appropriately. It may be the cause of the associated psychopathology.

(vii) Primary insomnia should be primarily treated by psychosocial interventions. The efficacy of short-term focused interventions has been strongly supported in young children and additional research is needed in the case of older children and adolescents.

(viii) Since stress and other psychosocial factors play an important role in most of the sleep disorders in children, it is important to assess these factors and intervene accordingly, even in those disorders which primarily require medical treatments.

(ix) Psychosocial and psychodynamic issues should always be addressed in the evaluation and treatment phases as underlying powerful factors in the evolution and maintenance of a child's sleep problem.

5.25.1 INTRODUCTION

Medically unexplained somatic symptoms are a common problem in adults and there is increasing evidence that these physical symptoms begin during childhood and adolescence (Kellner, 1986; Pilowsky, Bassett, Begg, & Thomas, 1982). Excessive somatic complaints and associated illness behavior can lead to serious developmental problems when accompanied by school absences, academic failure, and withdrawal from normal social activities. Moreover, the search for diagnoses and cures of these persistent physical complaints can place children at risk of unnecessary medical tests and treatments, which can be very expensive for the family, medical profession, and society. During this time of increasing attention to the cost of health care, there is a growing concern about the expenditure of both human and economic resources to deal with pediatric somatization. Several reviews of somatization in children (Campo & Fritsch, 1994; Campo & Garber, in press; Garralda, 1992, 1996; Nemzer, 1996) have highlighted the importance of this area to researchers and clinicians in both the psychiatric and medical communities. This chapter builds on these earlier reviews and further synthesizes the literature on somatoform disorders in children and adolescents.

5.25.2 HISTORY OF SOMATOFORM DISORDERS

The term *somat* is derived from the Greek word meaning body. As early as ancient Greece, the clinical entity of conversion symptoms was recognized. The word hysteria referred to physical symptoms that could not be explained medically. In the past, hysteria was thought to be a disorder in women due to abnormal movement of the uterus, and the term "somatization" was used to describe the belief that some neuroses could be manifested as bodily disorders (Steckel, 1943). Steckel defined somatization as a bodily disorder that arises as the expression of a deep-seated neurosis, "especially as a disease of the conscious" (p. 580). More recently, Lipowski (1988) defined somatization as "a tendency to experience and communicate somatic distress and symptoms unaccounted for by pathological findings, to attribute them to physical illness, and to seek medical help for them" (p. 1359).

Briquet (1859) was one of the first in modern times to observe a condition in which patients complained of multiple chronic, unexplainable physical symptoms. He also was one of the first to describe scientifically the syndrome of "hysteria." In the later 1800s, several physicians including Charcot, Bernheim, and Janet began treating hysterical symptoms with hypnosis. Freud (1896/1962) proposed that painful memories and affect from a traumatic event, typically of a sexual nature, can be "dissociated" from conscious awareness and then "converted" into somatic symptoms that symbolize an aspect of the trauma. Such dissociation and conversion were hypothesized to be the processes underlying hysterical symptoms.

Psychoanalytic theory changed the term hysteria to conversion hysteria, and in 1952 the *Diagnostic and statistical manual* (*DSM-I*) (American Psychiatric Association (APA), 1952) modified the term conversion hysteria to conversion reaction. Dissociative reaction referred to the mental manifestations of hysteria including amnesia, fugue states, and multiple personality. In 1968, *DSM-II* (APA, 1968) relabeled the categories to be "hysterical neurosis, conversion type" and "hysterical neurosis, dissociative type." *DSM-II* also created a category for the chronic multisystem somatoform disorder, and referred to it as "Briquet's syndrome." Separate categories were designated for "conversion disorder" and "dissociative disorder" and only parenthetically retained the term "hysterical neurosis" in *DSM-III* (APA, 1978) and *DSM-III-R* (APA, 1987). Some have questioned, however, whether conversion and dissociative disorders should be categorized separately because it is not unusual for both to occur in the same individual, and both disorders are characterized by psychological dissociation (Nemiah, 1985). *DSM-III* expanded the number of diagnoses under the rubric of somatoform disorders to include Body Dysmorphic Disorder, Hypochondriasis, and Somatoform Pain Disorder in addition to Conversion Disorder and Somatization.

Some of the specific criteria defining the various Somatoform Disorders have changed in *DSM-IV*. For example, whereas in *DSM-III* and *DSM-III-R* Conversion Disorder was broader and included autonomic symptoms (e.g., vomiting, endocrine dysfunction), *DSM-IV* has returned to a narrower set of criteria involving neurological symptoms. Autonomic symptoms that used to be part of the Conversion Disorder criteria in *DSM-III* now fall under the category of "undifferentiated somatoform disorder" or "somatoform disorder not otherwise specified." The separation of autonomic and sensory-motor symptoms in the criteria for defining conversion disorders has been questioned, particularly with regard to children in whom conversion-like disorders are particularly likely to be characterized by a mixture of motor, sensory, and autonomic symptoms (Looff, 1970).

The symptoms defining Somatization Disorder also have undergone several changes. In *DSM-III-R* any 13 symptoms from a list of 35 were required for the diagnosis. In *DSM-IV* a certain number of symptoms are required from each of the four physiological categories. This is more similar to the criteria outlined in *DSM-III*, which required a certain number of symptoms from each of six categories.

Thus, the specific names of the diagnoses that comprise somatoform disorders as well as the criteria that define them have undergone several changes with each new version of the *DSM*. This chapter focuses on somatoform disorders as defined by *DSM-III-R* and *DSM-IV*.

5.25.3 PHENOMENOLOGY

According to the fourth edition of the *Diagnostic and statistical manual of mental disorders* (*DSM-IV*; APA, 1994), "the common feature of Somatoform Disorders is the presence of physical symptoms that suggest a general medical condition ... and are not fully explained by a general medical condition, by the direct effects of a substance, or by another mental disorder" (p. 445). To receive a diagnosis of a somatoform disorder, the symptoms must cause clinically significant distress or impairment in social, occupational (academic), or other areas of functioning. Marital discord and diminished work performance are common. The group of conditions categorized as Somatoform Disorders do not necessarily share a common etiology or mechanism. Rather, they are classified together due to the clinical utility of needing to exclude medical conditions or substances as the cause of the bodily symptoms that comprise the disorders. Although each of the seven diagnoses included under the rubric of somatoform disorders has its own unique set of symptoms and criteria, they share several characteristics in common. Associated features often include depression, anxiety, suicidality, and impulsivity. It is not unusual for substance abuse to develop as a result of medications taken to alleviate the physical discomfort of the medical symptoms. Personality disorders, particularly histrionic, dependent, borderline, and antisocial are not uncommon. There also may be significant academic/occupational and social impairment due to frequent school or work absences and lack of involvement in normal social or extracurricular activities.

The course of somatoform disorders tends to be chronic with exacerbations of symptoms waxing and waning. Prognosis tends to be best when onset is acute, not complicated by personality disorders, associated with an identifiable stressor, and there is an absence of secondary gain as a result of symptom complaining (*DSM-IV;* APA, 1994).

Individuals with somatoform disorders typically take on the "sick role" and engage in illness behavior. Illness behavior is the manner in which individuals perceive and respond to somatic sensations that may or may not signify disease (Mechanic, 1972). Whereas most people pay little attention to such sensations, persons with somatoform disorders tend to interpret even normal sensations as indicating disease, and they respond by excessive complaining of symptoms, seeking medical treatment, and limiting their activities so that it interferes with their occupational/academic or social functioning.

"Exaggerated," "abnormal," or "medically unexplained" illness behavior has been examined extensively in adults (e.g., Pilowsky, 1987; Reesor & Craig, 1988) and is a problem not only for the individual who suffers from distress and impaired functioning, but also for society, which bears the costs associated with lost work days and overutilization of health services. Approximately 50% of physician visits are for complaints for which medical evaluation yields no evidence of disease (Barsky, Wyshak, & Klerman, 1986). Because individuals with somatoform disorders maintain the belief that there is something physically wrong with them, they often undergo many painful, expensive, and unnecessary medical tests and procedures in search of the presumed disease. They are generally not reassured by negative findings and therefore seek out multiple physicians ("doctor shop"), looking for one who will provide them with a medical explanation for their symptoms. They tend to be resistant to suggestions that their symptoms might be associated with psychosocial factors and they often ignore referrals to mental health professionals.

Despite speculation that symptoms of somatoform disorders and associated illness behavior begin in childhood, little is known about childhood forms and precursors of these diagnoses (Parmelee, 1986). Because children typically do not take themselves to the doctor, children with somatoform disorders must first convince their parents of the need to seek medical treatment. It also is not unusual for parents to share the belief that the child's symptoms require medical attention, thereby reinforcing or actually helping to generate the illness behaviors and beliefs in the child.

5.25.4 DIAGNOSTIC FEATURES

In *DSM-IV* (pp. 445–469), the Somatoform Disorders comprise seven distinct diagnoses: Somatization Disorder, Undifferentiated Somatoform Disorder, Conversion Disorder, Pain Disorder, Hypochondriasis, Body Dysmorphic Disorder, and Somatoform Disorder Not Otherwise Specified. Table 1 presents the *ICD-10* disorders that correspond to the somatoform disorders in *DSM-IV*. The criteria that define each of the *DSM-IV* somatoform disorders are the same for children, adolescents, and adults. These criteria are described briefly below.

5.25.4.1 Somatization Disorder

Somatization Disorder is characterized by a pattern of recurrent, multiple somatic complaints that cannot be explained fully by any known general medical condition or the direct effects of a substance. If a medical condition is present, the symptoms or associated dysfunction are in excess of what would be expected given the history or medical findings. The physical complaints must have begun before the age of 30 and have occurred over several years. Somatization disorder rarely is diagnosed in children; it is not uncommon, however, for symptoms to begin in adolescence with menstrual difficulties being one of the earliest symptoms in women. For a diagnosis of somatization disorder, a history of a certain number of symptoms are required in each of four areas: pain, gastrointestinal, sexual/reproductive, and pseudoneurological.

5.25.4.2 Undifferentiated Somatoform Disorder

Undifferentiated Somatoform Disorder is very similar to somatization disorder but fewer symptoms are required. It is defined by one or more medically unexplained, distressing, or impairing somatic complaints that persist for at least six months. Chronic fatigue or weakness of unknown medical origin, sometimes referred to as "Neurasthenia," would be given this diagnosis. Because a shorter duration and fewer symptoms are required, this may be a more appropriate diagnosis for children than somatization disorder.

5.25.4.3 Conversion Disorder

Conversion Disorder involves symptoms or deficits in voluntary motor or sensory functions that suggest a neurological or general medical condition. Conversion symptoms are referred to as "pseudoneurological" and include such problems as paralysis, blindness, and seizures. Because the onset or exacerbation of the symptom or deficit is preceded by conflict or other stressors, conversion disorder is believed to be associated with psychological factors.

5.25.4.4 Pain Disorder

Pain disorder is defined specifically by pain, which causes significant distress or impairment, and is of sufficient severity to warrant clinical attention. According to *DSM-IV*, two types of pain disorder can be identified: Pain Disorder Associated with Psychological Factors, and Pain Disorder Associated with Both Psycholo-

Table 1 Somatoform disorders in *DSM-IV* and *ICD-10*.

DSM-IV somatoform disorders		*ICD-10 somatoform disorders*	
300.81	Somatization disorder	F45.0	Somatization disorder
300.81	Undifferentiated somatoform disorder	F45.1	Undifferentiated somatoform disorder
300.81	Somatoform disorder not otherwise specified	F45.9	Other somatoform disorder
300.11	Conversion disorder	F44	Dissociative (conversion)
		F44.4–44.7	Dissociative disorder of movement and sensation
307.80	Pain disorder associated with psychological factors	F45.4	Persistent somatoform pain disorder
307.89	Pain disorder associated with psychological factors and a general medical condition		
307.7	Hypochondriasis	F45.2	Hypochondriacal disorder
300.7	Body dysmorphic		
		F45.3	Somatoform autonomic dysfunction
		F48	Other neurotic disorders
		F48.0	Neurasthenia

gical Factors and a General Medical Condition. In both subtypes, psychological factors are judged to play an important role in the onset, maintenance, and severity of the disorder. The primary difference is that in the latter diagnosis, both psychological factors and medical factors contribute to the onset and exacerbation of the pain. Several recurrent pain conditions in children would receive this diagnosis (e.g., recurrent abdominal pain, headaches, chest pain).

5.25.4.5 Hypochondriasis

In Hypochondriasis, the individual is preoccupied with fears of having or the belief of already having a serious disease despite medical reassurance to the contrary. The person misinterprets one or more bodily signs or symptoms such as heartburn, shortness of breath, or a minor cough as being indicative of a serious illness. The level of concern is not delusional, however, and the person can acknowledge that the fears may be unwarranted.

5.25.4.6 Body Dysmorphic Disorder

Body Dysmorphic Disorder is the preoccupation with some imagined or slight physical defect in appearance, particularly about flaws of the face or head (e.g., hair, nose, skin, eyes). Individuals often have difficulty controlling their preoccupation with the supposed deformity and may spend hours a day thinking about their "defect." In this respect, Body Dysmorphic Disorder (dysmorphophobia) is similar to obsessive-compulsive disorder (Phillips, McElroy, Keck, Pope, & Hudson, 1993).

5.25.4.7 Somatoform Disorder Not Otherwise Specified

Somatoform Disorder Not Otherwise Specified includes those cases with significant somatoform symptoms that do not meet all of the criteria for one of the somatoform disorders. Examples are when symptoms have been of shorter than the necessary duration (e.g., hypochondriacal symptoms for less than six months) or when the extent of functional impairment is less than clinically significant.

Table 2 summarizes information from *DSM-IV* concerning other characteristics of the five main somatoform disorders including age of onset, sex differences, cultural influences, prevalence, course, and associated features.

5.25.5 DIFFERENTIAL DIAGNOSIS

An important feature of somatoform disorders is that the symptoms are not produced voluntarily. This is in contrast to Factitious Disorder and Malingering, in which somatic symptoms are intentional and controllable. In the case of Factitious Disorder, symptoms are feigned in order to assume the sick role, whereas in Malingering symptoms are produced for some external incentive such as financial gain or avoidance of responsibilities. Factitious Disorder by proxy refers to situations in which a parent or caretaker produces, feigns, or stimulates disease in a child, with the incentive appearing to be an internal one for the caretaker.

Somatoform disorders also need to be distinguished from Psychological Factors Affecting Physical Conditions (PFAPC). In PFAPC there is a general medical condition that completely accounts for the physical symptoms but that is adversely affected by specific psychological or behavioral factors. These psychological factors tend to negatively influence the course or treatment of the medical condition. A common example of this is when the patient is noncompliant with a treatment regime (e.g., taking insulin for diabetes) due to emotional or behavioral problems.

5.25.6 COMORBIDITY

Comorbidity is defined as the co-occurrence of two or more disorders in the same individual at the same point in time. It is quite common for individuals with somatoform disorders to have other psychiatric problems and diagnoses including anxiety, depression, suicidality, impulsivity, substance abuse, and personality disorders. In an epidemiological study of psychiatric disorders in adults, Swartz, Landerman, and George (1991) reported that all persons with somatization disorder received another diagnosis, most commonly affective disorder, panic disorder, or simple phobia. In a community sample of adolescents, Taylor, Szatmari, Boyle, and Offord (1996) reported that about 42% of the youth who self-reported high rates of somatic complaints had at least one psychiatric diagnosis, most commonly an emotional disorder.

Several studies have found high rates of anxiety and mood symptoms and disorders among children with recurrent abdominal pain (RAP) (Garber, Zeman, & Walker, 1990; Hodges, Kline, Barbero, & Flanery, 1985a; Hodges, Kline, Barbero, & Woodruff, 1985b; Walker, Garber, & Greene, 1993; Wasserman, Whitington, & Rivera, 1988). Garber et al. (1990) conducted careful psychiatric interviews of children with RAP and found that 11 of 13 had an anxiety disorder and five of 13 had a

Table 2 Somatoform disorders (*DSM-IV*).

Disorder	*Somatization*	*Conversion*	*Pain*	*Hypochondriasis*	*Body dysmorphic*
Age	Onset must begin before age 30	Onset usually in late childhood to early adulthood	Can occur at any age	It can begin at any age, most commonly during early adulthood	Usually begins during adolescence
	Symptoms typically begin by adolescence	Onset rarely before age 10 year or after age 35 years			
	Rarely diagnosed before puberty	In children under 10 years old; gait problems or seizures are most common			
Gender	More common in women in US	More common in females than males (2:1 to 10:1)	Both males and females experience pain disorders	Equally common in males and females	About equal in males and females
	Higher rates in men in some cultures (e.g., Greece, Puerto Rico)	In women, conversion symptoms may develop into somatization disorder	Women experience more headaches than men		
		In men, associated with antisocial personality	Adolescent girls report more abdominal pain than boys		
Culture	Content of complaints varies with cultures	More common in lower SES, less educated, developing countries	Expressions of and responses to pain varies across cultures	Must consider cultural definitions of illness and what “healers” in their culture tell them about their illness	Culture can influence the extent of emphasis on appearance
	Sex ratio varies across cultures	Specific symptoms reflect local cultural ideas			
Prevalence	0.2–2% in women	1–3% of adult outpatients	Relatively common about 10–15% of adults have significant back pain	4–9% of patients in general medical practices	Little is known about its prevalence
	0.2% in men	Ranges from 11/100 000 to 300/100 000	About 10–15% of school children have abdominal pain		May be more common than previously thought

Table 2 (continued)

Disorder	*Somatization*	*Conversion*	*Pain*	*Hypochondriasis*	*Body dysmorphic*
Course	Chronic, but fluctuating Rarely remits	Onset is generally acute, but may have gradually increasing symptoms Episodes of acute symptoms are brief, but recurrent	Acute pain episodes tend to resolve after a brief duration Chronic pain can persist for years	Usually a chronic course, although symptoms may wax and wane	Onset may be gradual or abrupt Chronic course
Associated features	Functional disorders (e.g., irritable bowel syndrome)	*La belle indifference* Dissociation	With: psychological factors and/or general medical conditions Insomnia	May become homebound May have poor insight about excessiveness of complaints	Excessive grooming behavior and "mirror checking" Seek plastic surgery "Ideas of reference" about the presumed defect Eating disorders

mood disorder. Similarly, Wasserman et al. (1988) reported that 26 of 31 RAP patients had psychiatric disorders, with anxiety being the most common. Walker et al. (1993) reported that children with RAP had significantly higher levels of emotional symptoms than healthy controls, but less than children being evaluated in a psychiatric clinic specifically for emotional problems. Thus, children with RAP clearly have comorbid emotional problems, although their symptoms tend to be less severe than found among children receiving psychiatric treatment for anxiety and depression.

In their review, Bass and Murphy (1995) concluded that somatoform disorders are associated with very high rates of personality disorders and that the illness behavior of persons with somatoform disorders is "a lifestyle in which the sick role is a model of relating to self and others" (p. 424). They argued, therefore, that it might make more sense to think of the somatoform disorders as Axis II personality disorders rather than as Axis I disorders with comorbid personality disorders.

5.25.7 PREVALENCE

Epidemiological studies indicate that somatization disorder occurs in only 0.05–0.38% of the adult population (Swartz et al., 1991). The diagnosis of somatoform disorders is extremely rare in prepubertal children (Offord et al., 1987), although it has been diagnosed among adolescents. In a study of the six-month prevalence of child psychiatric disorders in a community sample, Offord et al. reported that somatization disorder was so rare among children 4–11-years old ($n = 1442$) that prevalence estimates for that age group could not be obtained reliably. Among adolescents aged 12–16 years, polysymptomatic somatization disorder was identified in 4.5% of boys ($n = 608$) and 10.7% of girls ($n = 624$). Thus, somatization disorder appears to increase with age and is about twice as common in adolescent girls as boys.

Other studies examining prevalence of child psychiatric disorders in pediatric (Costello et al., 1988) and community samples (Bird et al., 1988), however, have failed to report the rates of any of the somatoform disorders. This might be because somatoform disorders are considered to be so rare during childhood that researchers have decided that it was not worth the extra time to interview everyone about these syndromes. In addition, because information about actual medical status is needed to make the diagnoses, it is difficult to obtain this in large epidemiological studies. It is likely that it is for these reasons that somatoform disorders have been excluded from the various versions of the most frequently used interview in epidemiological studies (i.e., the Diagnostic Interview Schedule for Children, DISC; Costello; Edelbrock, Kalas, Kessler, & Klaric; 1982; Shaffer et al., 1996). Questions about somatoform disorders were not included in either the completed National Institute of Mental Health (NIMH)-funded Methods for the Epidemiology of Child and Adolescent Mental Disorders (MECA) study (Lahey et al., 1996) or the planned NIMH-funded Multi-Site Study of Mental Health Service Use, Need, Outcomes, and Costs in Child and Adolescent Populations (UNOCCAP) study. Therefore, the lifetime incidence and one-year prevalence rates of any of the Somatoform Disorders will remain unknown. A separate study in which both medical and psychiatric symptoms can be assessed in a large epidemiological sample is needed to determine more precisely the incidence and prevalence of somatoform disorders in children and adolescents.

Some children meeting the diagnostic criteria for somatization disorder have been identified in clinical samples (Kriechman, 1987; Livingston & Martin-Connici, 1985), but this is quite unusual. Several investigators have suggested that the *DSM* criteria are inappropriate for children, particularly given the fact that sexual and reproductive symptoms are required (Garber, Walker, & Zeman, 1991; Livingston & Martin-Connici, 1985). Other diagnoses such as undifferentiated somatoform disorder or pain disorder are probably more applicable to children.

In contrast to the finding that diagnosed somatoform disorders are rare in childhood, physical complaints have been shown to be quite common in children and adolescents (Garber et al., 1991; Goodman & McGrath, 1991). In a sample of 540 children in grades three through 12, Garber et al. assessed how frequently children had had each of 36 physical complaints in the preceding two weeks. About half the sample indicated on the Children's Somatization Inventory (CSI; Walker, Garber, & Greene, 1991; Walker & Greene, 1989, 1991a) at least one physical symptom during the prior two weeks; the most commonly reported symptoms were headaches, low energy, sore muscles, and abdominal discomfort. Factor analysis of the CSI revealed four symptom clusters that corresponded to four of the categories that defined somatization disorder in *DSM-III-R*: cardiovascular, gastrointestinal, pain/weakness, and pseudoneurological. About 1% of the sample endorsed at least 13 symptoms, and approximately 15% reported four or more symptoms. This was an important study because it provided information about the rates of self-reported somatic complaints across a wide age range. However, it is limited because independent medical assessments were not conducted to determine whether the reported physical symptoms were the result of actual disease. Thus, the rates of medically unexplained symptoms in children might be lower than that reported in this study.

Taylor et al. (1996) similarly conducted a community study with over 1000 Canadian adolescents (aged 12–16 years) and found the rates of some somatic symptoms and concerns to be quite high. About 50% (44.3–54.4%) of these teens reported that "their health should be better," headaches, worries about health, stomach aches or cramps, and aches and pains. Loss of functions (e.g., ability to swallow, voice, consciousness, hearing, sight) were reported much less frequently (2.9–7.5%). Although the rates of some individual symptoms were high, there did not appear to be a group of teens with extreme scores who might meet the criteria for somatization disorder. The average number of symptoms for those youth who had visited any medical service in the previous six months was 4.9, which is far below the 13 required for a diagnosis of somatization disorder.

Several other studies have found relatively high rates of somatic symptoms and concerns in children. The most common symptom is headaches, which has been reported in 10–30% of children and adolescents (Aro, Paronen, & Aro, 1987; Belmaker, Espinoza, & Pogrund, 1985; Larson, 1991; Oster, 1972; Rutter, Tizard, & Whitmore, 1970). Recurrent abdominal pain also is very common, reported in 10–24% of school-aged children and adolescents (Apley, 1975; Apley & Naish, 1958; Belmaker et al., 1985; Garber et al., 1991; Hyams, Burke, Davis, Rzepski, & Andrulonis, 1996). Other common somatic symptoms in children and adolescents are limb pains or so-called "growing pains" found in 5–20% of children (Apley, 1958; Belmaker et al., 1985; Garber et al., 1991; Larson, 1991; Oster, 1972), chest pain in about 7–15% (Belmaker et al.; Garber et al.), daily fatigue in about 15%, and 33.3–50% of adolescents complaining of fatigue weekly (Belmaker et al.; Larson, 1991), dizziness in about 15% of children (Garber et al.; Larson, 1991), and other gastrointestinal symptoms such as nausea and vomiting (Apley, 1975; Garber et al.; Larson, 1991). Worries about health also are common in children. Orr (1986) found that 40% of children and adolescents endorsed worrying about their health often, and 20% indicated they worried "all the time" about their health.

Pseudoneurological symptoms tend to be reported much less frequently (Garber et al., 1991; Rutter et al., 1970; Stefansson, Messina, & Meyerowitz, 1976). The most commonly reported conversion or pseudoneurological symptoms in children and adolescents are pseudoseizures, fainting, gait abnormalities, and sensory symptoms (Goodyer, 1981; Goodyer & Mitchell, 1989; Grattan-Smith, Fairley, & Procopis, 1988; Lehmkuhl, Blanz, Lehmkuhl, & Braun-Scharm, 1989; Leslie, 1988; Maloney, 1980; Spierings, Poels, Sijben, Gabreels, & Renier, 1990; Steinhausen, Aster, Pfeiffer, & Gobel, 1989; Volkmar, Poll, & Lewis; 1984).

5.25.7.1 Age Effects

Somatoform disorders are rarely diagnosed before puberty, although specific somatic complaints are not uncommon during childhood. For example, the rate of recurrent abdominal pain peaks at about age nine and the rate of headaches peaks about age 12 (Oster, 1972), and even preschoolers have been reported to have somatic symptoms (e.g., stomach aches, vomiting) associated with psychological distress (Prugh, 1983). Pseudoneurological symptoms and diagnosed conversion disorder are extremely rare before age six, but increase with age particularly during adolescence (e.g., Lehmkuhl et al., 1989; Stefansson et al., 1976; Volkmar et al., 1984). Similarly, polysymptomatic complaints become increasingly more common during adolescence (Achenbach, Conners, Quay, Verhulst, & Howell, 1989; Offord et al., 1987). Although all the criteria for somatization disorder are rarely met in childhood, the majority (55%) of adults receiving a diagnosis of somatization disorder report experiencing their first somatic symptoms before age 15, and their symptoms tended not to remit (Swartz et al., 1991). Thus, not all symptoms that comprise somatoform disorders may be present across development, although it is likely that some symptoms and precursors of these disorders can be observed by early adolescence.

5.25.7.2 Sex Differences

Table 2 shows the rates of each of the somatoform disorders in men and women as reported in *DSM-IV*. There are some differences between children and adults in the rates of somatoform disorders in girls vs. boys. Prior to puberty the prevalence of somatization disorders is about equally rare in girls and boys. With the onset of puberty and menarche in girls, there tends to be an increase in the rates of somatic complaints in girls compared to boys (Aro & Taipale, 1987; Belmaker, 1984). There appears to be a decline in symptom reporting among adolescent boys (Garber et al., 1991). Moreover, girls tend to be more consistent than boys in reporting somatic symptoms over time (Rauste-von Wright & von Wright, 1981; Walker & Greene, 1991b).

Pseudoneurological or conversion symptoms have also been found to be more prevalent in females than males, and this begins to become apparent during adolescence (Lehmkuhl et al., 1989; Turgay, 1980; Volkmar et al., 1984). Among prepubertal children, some studies have found the rates of conversion disorder to be about equal for boys and girls (Stevens, 1986), whereas other studies have reported the rates to be higher among girls than boys (Goodyer, 1981; Volkmar et al., 1984).

The greater rate of somatic complaints among adolescent girls than boys could be due to several factors. There may be an actual rise in the number and types of somatic symptoms girls experience during adolescence, particularly due to symptoms associated with their menstrual cycle. It also is possible, however, that the discrepant rates are due to sex differences in reporting tendencies. Girls may be more willing to express their distress to others and might view it as a legitimate means of obtaining social support. Indeed, girls generally seek support from others more than boys (Belle, Burr, & Cooney, 1987), and in particular girls seek care for their physical complaints more than boys (Lewis & Lewis, 1989). Moreover, in a study of children's use of emotion display rules, Zeman and Garber (1996) found that girls reported they would be significantly more likely than boys to express pain. In addition, compared to boys, girls reported that they thought other people would be more accepting and understanding of their expressions of emotions. Thus, boys may be less willing to endorse somatic symptoms because they think others will be less tolerant of such complaints or see it as unmasculine.

These sex differences could have their roots in children's socialization history. For example, Walker and Zeman (1992) found that parents encouraged illness behavior more in girls than in boys. Fuchs and Thelen (1988) found that children reported that their parents reacted differently to the emotional displays of girls vs. boys. In general, parental socialization pressures tend to be perceived by children to be directed toward the masking of distress in boys vs. girls.

Thus, there appear to be sex differences in the rates of somatic complaints and illness behavior in children, and this becomes particularly apparent during adolescence. These differences could be the result of girls actually experiencing more somatic distress than boys, as well as to girls' greater willingness to express this distress to others.

5.25.7.3 Sociocultural Factors

Although it is likely that social, cultural, and ethnic factors might influence the development and expression of somatic complaints (Kirmayer, 1984), there has been little research on this issue in children. Whereas some studies have found an association between somatoform disorders in children and low socioeconomic status (SES), low levels of parental education, or living in a rural area (Aro et al., 1987; Proctor, 1958; Steinhausen et al., 1989), other studies have not found such a relation (Stevenson, Simpson, & Bailey, 1988; Walker & Greene, 1991a). In developing countries, 1.3–5% of child psychiatry outpatients have been found to have conversion disorders (Herman & Simonds, 1975; Proctor, 1958).

It is possible that cultural factors influence the presentation of somatic symptoms and may contribute to the higher incidence of conversion disorder in less-developed countries. Prazar (1987) asserted that less sophisticated individuals are more likely to present with symptoms that are not easily explained physiologically, although he argued that there is no relation between conversion symptoms and SES. In contrast, Taylor et al. (1996) found in a community sample of Canadian adolescents a significant association between poverty and somatic complaints. It is possible, however, in the Taylor et al. study that these somatic symptoms reflected real illnesses due to their less favorable living conditions.

Studies in Turkey (Turgay, 1980) and India (Srinath, Bharat, Girimaji, & Seshadri, 1993) have found conversion symptoms to be a common presentation of psychiatric disorders. For example, Srinath et al. (1993) reported that conversion disorder (mostly pseudoseizures) was diagnosed in 30% of inpatients and 15% of outpatients.

Weisz and colleagues (Weisz et al., 1987; Weisz et al., 1993) have compared the behavioral and emotional problems of children and adolescents in the US vs. Thailand. Weiss et al. (1987) found that among children aged 6–11 years, five of the six differences that were considered to be medium to large effects involved somatic difficulties. Thai children were rated by their parents to be higher on "doesn't eat well," "constipated," "feels dizzy," and "underactive, lacks energy." Thai adolescents also were rated higher on the latter three symptoms (Weisz et al., 1993). However, Thai children were not more likely than American children to have the most common somatic complaints such as headaches and stomach aches. Thai children were rated higher than American children on overcontrolled behaviors. Weisz et al. (1987, 1993) suggested that there probably are more cultural pressures in this Asian society for children to have self-control, emotional restraint, and social inhibition. It could be that such societal demands increase the likelihood of children expressing their distress somatically rather than behaviorally.

5.25.8 ETIOLOGY

Multiple factors have been proposed to explain the etiology of somatoform disorders including genetics, personality, somatic and perceptual sensitivity, family processes, stress and trauma, and emotional communication. Because of the heterogeneity of somatoform disorders, it is likely that different models will explain the specific disorders that comprise this category. It is also likely that a more complex biopsychosocial model that incorporates different aspects of various perspectives will ultimately explain the processes leading to the development of somatoform disorders.

5.25.8.1 Genetics and Personality

Somatization is clearly familial (Edwards, Zeichner, Kuczmierczyk, Boczkowski, 1985; Garber et al., 1990; Kriechman, 1987; Routh & Ernst, 1984; Walker et al., 1991; Wasserman et al., 1988), which is likely due to a combination of genetic and environmental factors. Adoption studies have found somatization disorder to be over five times more common in female first-degree relatives of probands with somatization than in the general population (Cloninger, 1986). Twin studies, on the other hand, have not provided much evidence of a strong genetic contribution to the development of somatization (Gottesman, 1962; Inouye, 1972; Torgensen, 1986), although there might be a genetic factor for somatic anxiety (Kendler, Heath, Martin, & Eaves, 1987).

Cloninger and colleagues (Bohman, Cloninger, von Knorring, & Sigvardsson, 1984; Cloninger, Sigvardsson, von Knorring, & Bohman, 1984; Guze, Cloninger, Martin, & Clayton, 1986) have also found genetic links between somatization disorder and antisocial personality and alcoholism. The biological fathers of adopted-away women who were "high-frequency somatizers" tended to have a history of violent crime (Cloninger, 1986). Cadoret (1978) similarly found that adopted-away daughters of antisocial patients were more likely to suffer medically unexplained somatic symptoms compared to controls. Studies of somatizing children have also found high rates of externalizing disorders among their relatives (Kriechman, 1987; Routh & Ernst, 1984).

Shields (1982) proposed that the personality traits that predispose to somatization may be what is inherited rather than somatization *per se*. Cloninger (1986) suggested that persons with somatization disorder are characterized by distractibility, impulsivity, and failure to habituate to repetitive stimuli. It is possible that these traits contribute to the link between somatization and antisocial personality disorder.

In a study specifically designed to assess personality, Stern, Murphy, and Bass (1993) reported that 72% of somatization patients compared to only 36% of controls had personality disorders, particularly passive-dependent, histrionic, and sensitive-aggressive. Tyler, Fowler-Dixon, and Ferguson (1990) have described a hypochondriacal personality disorder that presumably underlies somatization disorder and includes excessive preoccupation with health, distorted perceptions of minor symptoms, and frequent medical consultations. In children, excessive somatic complaints have been associated with obsessiveness, conscientiousness, hypersensitivity, insecurity, lack of perceived competence, anxiety, and possibly behavioral inhibition (Cunningham et al., 1987; Garralda, 1992; Kagan, Reznick, & Snidman, 1988; Walker et al., 1993). The extent to which these temperamental features during childhood become personality disorders that then predispose individuals to develop adult somatoform disorders needs to be explored further.

5.25.8.2 Somatic and Perceptual Sensitivity

Individuals with somatoform disorders have also been hypothesized to have greater somatic and/or perceptual sensitivity (Barsky & Klerman, 1983; Kellner, 1990). Various forms of normal physiological arousal and bodily changes are associated with somatizing symptoms. For example, contractions of the scalp muscles are observed with headaches (e.g., Fujii, Kachi, & Sobue, 1981; Sainsbury & Gibson, 1954); elevated electromyograph levels in paravertebral muscles can be found in patients with lower back pain (Dolce & Raczynski, 1985; Flor, Turk, & Birbaumer, 1985); contractions of smooth muscle in the alimentary tract are common in abdominal pain patients (Whitehead & Schuster, 1985), and esophageal motility is found in persons with chest pain (Clouse & Lustman, 1983). These normal physiological reactions can develop into more persistent or severe symptoms in several ways. First, somatizers might have a more sensitive physiological system such that they respond more intensely than normals to the same level of physical stimulation. Second, even if their initial response is within the normal range, they might have a more sustained physiological reaction and a slower return to baseline. Third, it is possible that somatizers respond normally physiologically, but simply attend to their symptoms more than others. Finally, somatizers also might misinterpret their normal bodily sensations as indicating a more serious condition than is warranted.

It is likely that individuals differ in their degree of somatic sensitivity, that is, the intensity with which they experience a particular level of somatic stimulation. Moreover, under conditions of stress, high somatic sensitivity will increase the likelihood that symptoms of affective arousal will be translated into somatic symptoms. The existing evidence in children relevant to this hypothesis is mixed. Using a painful cold pressor stimulus, Feuerstein, Barr, Francoeur, Houle, and Rafman (1982) did not find any meaningful differences in the autonomic, subjective, or behavioral responses of children with RAP compared with healthy controls. In contrast, using lower intensity stimulation with an algometer, Alfven (1993) reported that RAP children had significantly lower pressure pain thresholds than well children. Thus, if somatizers are hypersensitive to physical stimulation, this might be particularly apparent at lower levels of stimulation and for some forms of stimulation but not others.

Even if somatizers do not respond more sensitively initially to somatic stimulation, it also might be that they have a more prolonged somatic reaction once exposed. The reasons for this sustained reaction could be either physical or psychological; that is, once aroused it simply might take more time for their physiology to return to baseline, and therefore they experience the symptoms longer. It also is possible, however, that individuals who somatize are more likely to continue to attend to their symptoms, thereby sustaining a higher level of arousal for a longer period of time.

The extent to which individuals attend to normal bodily sensations can be learned. For example, Pennebaker and Skelton (1978) found that the instructions given to subjects could influence whether or not they perceived a bodily sensation. Moreover, habitual attention to somatic symptoms in certain parts of the body is likely to increase one's perceptions of sensations in that area, (Kellner, 1986). Such attentional variation can lead to either an amplification or minimization of bodily sensations (Barsky, Goodman, Lane, & Cleary, 1988; Mayou, 1976).

Finally, normal physiological reactions are sometimes misinterpreted as reflecting a more serious somatic problem, that is, whereas most individuals normalize common symptoms and attribute them to minor physical variation or environmental factors, individuals who somatize tend to attribute such normal bodily symptoms to much more pathological causes (Robbins & Kirmayer, 1991). This misinterpretation itself could increase the amount of stress experienced by the individual, and thereby lead to a more severe or sustained somatic reaction.

Thus, individuals with somatoform disorders are hypothesized to have an increased somatic and/or perceptual sensitivity. Somatic sensitivity is likely the result of a more severe initial physiological response to stimulation or a more sustained reaction with a slower return to baseline. Perceptual sensitivity is reflected by a normal physiological reaction that receives greater attention or that is misinterpreted as reflecting a more serious somatic problem.

5.25.8.3 Family Processes

The family environment can influence the development of somatization symptoms in children in several ways. Although the specific amount of genetic vs. environmental factors which contribute to the high rates of somatization in relatives of children with somatoform disorders is unclear, the presence of "ill" persons in the family environment can influence the child's psychological development through such processes as modeling and reinforcement (Craig, 1978; Fordyce, 1978; Turkat, 1982). Walker et al. (1993) suggested that the high numbers of potential models of illness behavior in families of children with recurrent abdominal pain provide more opportunities for vicarious learning of such behavior and for the observation of these models receiving reinforcement of their illness behavior (Whitehead, Busch, Heller, & Costa, 1986).

Operant learning can also play a role in the development and maintenance of recurrent pain in children (McGrath, 1987) and in the reduction of symptoms and disability (Sanders et al., 1989; Sank & Biglan, 1974). Positive reinforcement of expressions of pain (Osborne, Hatcher, & Richtsmeier, 1989) and discouragement of adaptive coping responses have been found to be associated with higher rates of illness behavior in children (Dunn-Geier, McGrath, Rourke, Latter, & D'Astous, 1986). Walker et al. (1993) found that children with abdominal pain reported that their parents responded more frequently to their symptom complaints with increased attention and special privileges compared to well children.

Whereas some have reported that parental lack of care and childhood illness significantly predicted adult somatization (Craig, Boardman, Mills, Daly-Jones, & Drake, 1993), others have suggested that parents of somatizing children are overprotective and promote separation fears (Grattan-Smith et al., 1988; Lehmkuhl et al., 1989; Robinson, Alverez, & Dodge, 1990) which can increase children's sense of vulnerability and fragility (Green & Solnit, 1964). The children's somatic symptoms can serve to maintain proximity to important attachment figures (Henderson, 1974; Wooley, Blackwell, & Winget, 1978) and may be the consequence of children's anxiety about being separated from such persons (Garber et al., 1990; Hodges et al., 1985b).

Family system theorists have suggested that psychosomatic symptoms can serve a function within the family system to avoid conflict, particularly between the parents (Minuchin et al., 1975; Minuchin, Rosman, & Baker, 1978; Mullins & Olson, 1990). Disturbed patterns of communication, cohesion, and support have been reported among families of children with somatoform disorders (Maloney, 1980; Walker, McLaughlin, & Greene, 1988; Wasserman et al., 1988), although not necessarily worse than families of children with emotional disorders (Walker et al., 1993). In somatizing families, physical symptoms often become the means of communication of distress, and are the focus of attention rather than the relationship problems that exist among family members (Lask & Fosson, 1989; Maisami & Freeman, 1987).

Wood (1993) proposed a biobehavioral family model that focuses on the mutual influence of individual factors, such as psychophysiologic reactivity, and family patterns, such as parental discord, triangulation, and negative affectivity. She suggested that high levels of individual psychophysiologic reactivity and stressful family patterns will potentiate one another and interact to influence the outcome of disease processes. This model needs to be tested further with regard to children with somatoform disorders in particular.

Thus, socialization processes can contribute to the development of excessive somatic complaints in children (Parmelee, 1986) and the eventual onset of somatoform disorders. Further research is needed in which the actual behaviors of parents in response to their children's somatic complaints is observed. Longitudinal studies are also needed to untangle the direction of causality between parenting behavior and child symptoms. Such studies can serve as a basis for interventions aimed at preventing the development and maintenance of somatization symptoms and disorders.

5.25.8.4 Stress and Trauma

Higher levels of negative life events have been found to be associated with greater frequency of illness episodes and health service utilization (Beautrais, Fergusson, & Shannon, 1982; Boyce et al., 1977; Roghmann & Haggerty, 1973), symptom maintenance, and illness exacerbations (Chase & Jackson, 1981; Perrin, MacLean, & Janco, 1988). Among children with somatization disorders in particular, some studies have found an association with stressful life events (Aro, 1987; Greene, Walker, Hickson, & Thompson, 1985; Hodges et al., 1985a; Pantell & Goodman, 1983; Robinson et al., 1990; Scaloubaca, Slade, & Creed, 1988; Walker & Greene, 1987), whereas other studies have failed to find such a relation (McGrath, Goodman, Firestone, Shipman, & Peters, 1983; Turgay, 1980; Walker & Greene, 1991a; Wasserman et al., 1988). The life-event profiles of children with somatizing disorders have been found to be similar to those of children with psychiatric disorders and different from healthy controls (Hodges et al. ; Scaloubaca et al., 1988; Turgay, 1980), although other studies have reported that children with recurrent pain experience fewer negative life events than children with emotional disorders (Walker et al., 1993). The different results across these studies may be due to differences in the types of psychiatric comparison groups studied and in the types of life events assessed. For example, children with somatizing problems tend to report a greater number of events involving family illness in particular compared to healthy and psychiatric children (Hodges et al.; Walker et al.; Wasserman et al.). There also is some evidence that early loss is linked to somatization and recurrent pain (Mallouh, Abbey, & Gillies, 1995; Wasserman et al.).

It also is possible that stress is a general risk factor that contributes to the onset and maintenance of many types of disorders. The more interesting and important question is what factors in combination with stress make some people vulnerable to one disorder rather than another. That is, what is the particular model in which stress is a part that predicts specific disorders (Garber & Hollon, 1991)? In a prospective study of 197 pediatric patients with chronic abdominal pain, Walker, Garber, and Greene (1994) found that among children who had high levels of negative life events, those who had been reported to be low in social competence had higher levels of somatic complaints one year later compared to children who were high in social competence. In addition, Walker et al. found that among boys who experienced high levels of negative life events, those whose mothers were characterized by high levels of somatic symptoms had higher levels of somatic symptoms a year later. Thus, both social competence and maternal somatic complaints moderated the relation between stress and somatization in pediatric patients. This indicates that a more complex model which includes stress in combination with other psychosocial factors may be needed to explain the onset and maintenance of somatization in children. The extent to which such a model generalizes to normative populations needs to be studied further.

Traumatic life events, particularly physical and sexual abuse, have also been linked to somatization. Early theories suggested that childhood trauma was a factor in most cases of hysteria (Briquet, 1859; Freud, 1896/1962). Despite the general rejection of Freud's "seduction theory," there continues to be an interest in the association between childhood physical and sexual abuse and somatic and conversion symptoms (Green, 1993; Loewenstein, 1990; Morrison, 1989; Rimza, Berg, & Locke, 1988). Pseudoneurological symptoms (e.g., pseudoseizures), genitourinary and gastrointestinal symptoms, in particular, have been observed among victims of sexual abuse (Bowman, 1993; Goodwin, Simms, & Bergman, 1979; Hunter, Kilstrom, & Loda, 1985; Klevan & DeJong, 1990; LaBarbera & Dozier, 1980). Prospective studies of abused children are needed to establish the predictive link between early trauma and subsequent somatoform symptoms and disorders.

5.25.8.5 Emotional Communication

Traditional psychodynamic theory has been particularly prominent in the explanation of conversion disorder. According to this view, an unconscious intrapsychic conflict, wish, or need is "converted" into a somatic symptom, which presumably expresses symbolically some aspect of the conflict while at the same time protecting the person from conscious awareness (Engel, 1962). Critics of this perspective argue that the evidence is limited concerning the symbolic meaning of the symptom and its link to the unconscious.

More modern approaches assert that somatizing is a psychological defense whereby individuals experience and express emotional distress physically rather than acknowledge unpleasant affects, memories, or conflicts (Shapiro & Rosenfeld, 1987; Simon, 1991). Constructs such as alexithymia (Nemiah, 1977; Sifneos, 1973) and the defensive style of "repression" (Weinberger, Schwartz, & Davidson, 1979) have been proposed to explain the association between somatic symptoms and reduced emotional awareness and expression.

Alexithymia is characterized by difficulties in identifying and describing feelings, difficulty distinguishing between feelings and the bodily sensations of emotional arousal, limited imagination and fantasy life, and a concrete and reality-based cognitive style (Taylor, Baglay, Ryan, & Parker, 1990). Adult patients with somatization disorder have been found to have higher scores on a self-report measure of alexithymia compared to patients with other psychiatric disorders (Bagby, Taylor, & Parker, 1994; Taylor et al., 1990), although alexithymia has also been found to be associated with depression, neuroticism, and eating disorders (Bourke, Taylor, Parker, & Bagby, 1992; Cohen, Auld, & Brooker, 1994; Wise & Mann, 1994). More research needs to be conducted regarding the measurement and construct validity of alexithymia in adults, and its particular relation to somatoform disorders. There also has been almost no research on alexithymia in children.

Because young children have limited cognitive and linguistic abilities, it is not unusual to hear them express their emotional distress with physical symptoms. This might be particularly apparent in those families or cultures in which the expression of emotional distress is discouraged, whereas somatic complaints receive acceptance and attention (Escobar, Burnam, & Karno, 1987). Although there is a large developmental literature concerning the emergence of emotional competence in children (e.g., Saarni, 1990), little is known about the emotional development of children with somatoform disorders. Children who somatize might be especially likely to show delays or deviation in their emotional competence, particularly regarding emotional identification and expression; that is, they might be less competent at linking affects with situations, or expressing emotions in certain contexts, particularly those involving negative affect. Thus, although there has been considerable theoretical speculation about the role of affect expression and emotional competence in the development of somatization, the relevant empirical investigations have not yet been conducted.

5.25.9 COURSE AND PROGNOSIS

There have been few systematic longitudinal studies of children and adolescents with somatoform disorders and therefore little is known about their course and prognosis. Studies have varied with regard to the types of patients and disorders studied, the length of the follow-ups, and the specificity vs. generality of the outcomes assessed. In general, acute onset of fewer and transient symptoms tends to have a better prognosis than insidious onset of multiple symptoms that are recurrent or chronic (Ernst, Routh, & Harper, 1984; Grattan-Smith et al., 1988; Robins & O'Neal, 1953), although the findings have not always been consistent with this perspective (Goodyer & Mitchell, 1989; Lehmkuhl et al., 1989).

Several follow-up studies of children and adolescents with RAP have revealed that many (25–50%) of these patients continue to experience somatic complaints as adults (Apley & Hale, 1972; Christensen & Mortensen, 1975; Liebman, 1978; Stickler & Murphy, 1979; Stone & Barbero, 1970; Walker, Garber, Van Slyke, & Greene, 1995). In a five-year follow-up study, Walker et al. (1995) found that children and adolescents originally diagnosed with RAP reported significantly higher levels of abdominal discomfort, other somatic symptoms, and functional disability than formerly healthy controls. Moreover, the former RAP patients had higher levels of internalizing emotional symptoms (e.g., anxiety and depression) and significantly higher levels of mental health service utilization than the healthy comparison group. With regard to pseudoneurologic or conversion symptoms, studies have found that over 50% of patients with such symptoms tend to show significant clinical improvement or recovery, although a subset of children with conversion disorders go on to develop somatization disorder or other psychiatric problems including anxiety and personality disorders (Bangash, Worley, & Kandt, 1988; Goodyer, 1981; Goodyer & Mitchell, 1989; Grattan-Smith et al., 1988; Kotsopolous & Snow, 1986; Lehmkuhl et al., 1989; Leslie, 1988; Maisami & Freeman, 1987; Proctor, 1958; Schneider & Rice, 1979; Spierings et al., 1990; Turgay, 1990; Wyllie et al., 1991). Kotsopoulos and Snow (1986) reported that 40% of 20 children with conversion disorder continued to have somatic or psychiatric symptoms 1–3 years after the initial assessment.

There is also evidence that some children originally diagnosed as having a somatoform disorder (e.g., conversion disorder) were later discovered to have had or to have developed a medical condition that explained their earlier symptoms (Robins & O'Neil, 1953; Woodbury, De Maso, & Goldman, 1992). Some researchers have argued, however, that early subclinical impairments in medical disorders, such as multiple sclerosis or tumors of the nervous system, might trigger a vulnerable person to develop conversion symptoms (Caplan & Nadelson, 1980; Nemzer, 1996; Rivinus, Jamison, & Graham, 1975). Thus, careful follow-up studies are needed to examine the continuity of somatic symptoms over time and to explore the extent to which diagnoses of somatoform symptoms and disorders were originally or subsequently develop into actual medical conditions.

5.25.10 CONCEPTUALIZATION AND CLINICAL FORMULATION

5.25.10.1 Assessment

There are few standard methods and measures for assessing somatoform disorders in children and adolescents. Comparisons across studies are difficult because different criteria and different instruments containing different lists of symptoms have been used. Assessment and diagnosis of somatoform disorders is especially challenging because independent medical assessments are needed to determine whether the reported physical symptoms are the result of identifiable organic disease and, if there is organic disease, whether there is functional impairment beyond what would be expected. Furthermore, the diagnosis of somatoform disorders is not simply a matter of the absence of medical findings. Rather, clinicians need to conduct a careful assessment to determine whether the patient meets the various symptom criteria for a somatoform disorder as well as for any other psychiatric diagnoses.

Another difficulty in assessing and diagnosing childhood somatoform disorders is that, in contrast to children with most other kinds of psychiatric problems, children with somatoform disorders are typically brought to pediatricians and general practitioners rather than to psychiatrists or psychologists. It is critical that physicians lay the groundwork for possible psychosocial intervention by explaining to the child and family that the routine comprehensive evaluation involves assessing both physical and psychological factors. Presented in this way, physicians can reduce resistance by the patient and family to inquiries about emotional issues that they might view to be private and irrelevant to the medical condition for which they are seeking help.

In addition to conducting a physical examination and obtaining a complete medical history, the pediatrician or family practitioner also should get a psychosocial history, an assessment of any recent stressors, and conduct a thorough mental status examination. Physicians are obviously quite adept at performing the necessary medical evaluations to detect physical illness, however, they often miss the psychiatric symptoms in children (Costello & Edelbrock, 1985). This is partially due to their lack of experience with the methods for evaluating psychiatric symptoms in children. Therefore, it is important for physicians to have screening measures that they can use to identify those patients for whom referral for further psychiatric evaluation might be appropriate.

Several commonly used psychological instruments are available for assessing somatic complaints as well as other emotional and behavioral problems in children. The Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1983) has versions for parents, teachers, and children to complete. A somatic complaints subscale can be derived from the CBCL. The Personality Inventory for Children (PIC; Wirt, Lachar, Klinedinst, & Seat, 1984), which is a personality questionnaire completed by parents about their children, also contains a somatic complaints subscale. Neither the CBCL nor the PIC, however, can be used to diagnose somatoform disorders (Prichard, Ball, Culbert, & Faust, 1988). This is largely because the extent to which somatic symptoms are the result of an actual organic problem requires an independent medical evaluation. There are also measures that assess somatic complaints in particular. The CSI (Garber et al., 1991; Walker et al., 1991; Walker & Greene, 1989) was developed explicitly to assess symptoms of somatization disorder in children and adolescents. The CSI includes symptoms from the *DSM-III-R* (APA, 1987) criteria for somatization disorder and from the somatization factor of the Hopkins Symptom Checklist (Derogatis, Lipman, Rickels, Uhlenhuth, & Covi, 1974). Children rate the extent to which they have experienced each of 35 symptoms in the last two weeks using a five-point scale ranging from 0 = not at all to 4 = a whole lot. A total score, obtained by summing the ratings, can range from zero to 140. Both test–retest reliability and internal consistency for the CSI have been found to be quite good (Walker et al.). There also is a parent form of the Children's Somatization Inventory (P-CSI) that includes the same symptoms as the CSI and is completed by parents with reference to their children.

A similar questionnaire was developed by Benjamin and Eminson (1992) that measured lifetime prevalence of symptoms in 11–16-year-old British children. They found that somatic and emotional symptoms were correlated, particularly in girls. About 20% of the children reported worries about health that affected their school attendance.

The Ontario Child Health Study used a 17-item list containing questions about the experience of bodily distress, worries and concerns about health, and the experience of having lost faculties for no apparent reason. Items were checked either 0 = never or not true, 1 = sometimes true, or 2 = often or very true. A total "somasick" score can be calculated by adding items marked one or two, yielding a possible total score of 34. Psychometric properties of this scale have not been reported (Taylor et al., 1996).

Thus, when physicians suspect the possibility of a somatoform disorder in children, their assessment should include a thorough physical exam to rule out medical explanations for the child's symptoms, general measures of child behavioral and emotional symptoms (e.g., CBCL), more specific measures of the most likely emotional problems including anxiety and depression (e.g., Children's Depression Inventory, Kovacs, 1980/1981; Revised Children's Manifest Anxiety Scale, RCMAS, Reynolds & Richmond, 1985), specific measures of somatic complaints (e.g., CSI), and an assessment of the extent of impairment and functional disability due to the somatic symptoms (e.g., Functional Disability Inventory, FDI; Walker & Greene, 1991b). Although the physician will still not be able to make a diagnosis of a somatoform disorder on the basis of these instruments, these measures will provide important information to guide decisions about the possible need for further medical and psychological evaluation.

It also is generally considered to be a good idea to obtain information from multiple sources, although there are known problems with lack of agreement across informants (Achenbach, McConaughy, & Howell, 1987). Who is the best source of information regarding children's somatic problems? Because somatic symptoms are primarily subjective, it is crucial to ask the children themselves. Parents and teachers can be useful informants, however, about the onset and duration of children's physical complaints and the extent of impairment associated with these complaints, such as not playing with friends or not doing school work.

Results of studies examining the relation between parent and child report about somatic complaints have differed as a function of the sample used. Taylor et al. (1996) explored in a community sample the extent of agreement between adolescents and their parents' reports about the teens' somatic symptoms using the 17-item questionnaire from the Ontario Child Health Study. They found a high correlation between parents and youth ($r = 0.80$), but little agreement on the endorsement of specific symptoms (all kappas were less than 0.30).

Garber, Van Slyke, and Walker (1997) studied mother–child concordance regarding children's somatic and emotional symptoms in children diagnosed with either a physical, emotional, or no disorder. Whereas well children and their mothers showed a high level of concordance, mothers of children with recurrent abdominal pain reported more child somatic and emotional symptoms than their children. Discordance was in the direction of mothers reporting more symptoms in their children than the children themselves, and this was associated with higher levels of maternal distress. Thus, obtaining reports from multiple sources can provide useful information from different perspectives, although the level of concordance is likely to be low.

Finally, given the presumably unconscious nature of conversion symptoms, they are likely to be particularly difficult to assess. The Dissociative Experiences Scale is a self-rating scale that has been used to measure dissociative symptoms in adults (Bernstein & Putnam, 1986) and children (Putnam, Helmers, & Trickett, in press). When other diagnostic procedures have been exhausted, sodium amytal interviews are sometimes tried. Weller, Weller, and Fristad (1985) described several case studies in which they used amytal interviews with children to remove conversion symptoms and to differentiate between feigned and actual symptoms. Weller et al. (1985) concluded that a properly administered amytal interview can be a safe and effective diagnostic and therapeutic tool with children.

An interesting technique for diagnosing pseudoseizures is video-electroencephalographic monitoring. During a seizure, the patient is simultaneously videotaped and the EEG recorded. If there is no electrical brain activity, the seizure is assumed to be a conversion symptom (Nemzer, 1996).

Thus, the assessment of somatoform disorders in children and adolescents should involve multiple methods including child self-report inventories, parent questionnaires, psychiatric interviews, medical evaluations, family histories, and amytal interviews when appropriate. More research needs to be conducted to determine the best way to integrate the information obtained from these various methods and sources.

5.25.10.2 Treatment Formulation

Because patients with somatoform disorders tend to think of their symptoms as resulting from medical rather than psychological causes, they can be particularly reluctant to seek or accept psychological explanations for their symptoms, and they may be resistant to psychosocial interventions. Therefore, it is important for health-care workers to acknowledge the reality of the patient's physical distress and also to provide reassurance that the symptoms are not severe or life-threatening (Kellner, 1991; Maisami & Freeman, 1987), although too much reassurance should be avoided (Warwick & Salkovskis, 1985).

Routine use of an interdisciplinary team comprised of physicians, nurses, psychologists, and social workers can be especially helpful because it communicates to the patient and family that all aspects of the child's health are being considered, and it can provide a coordinated management approach (Mayou, Bass, & Sharpe, 1995). The treatment team can explain to patients that their physical problems can also have emotional consequences. This is sometimes a good way of introducing the need for psychological assessment and possible psychosocial intervention. At least at first, it is probably not necessary for patients with somatoform disorders to believe that psychological factors played a role in the development or maintenance of their symptoms. After some rapport has been developed with the patient, however, the possible contribution of psychological factors to their symptoms can and should be discussed. Moreover, the diagnosis of a somatoform disorder can be presented as "good news" if it means the absence of a serious medical condition. When a referral is made for mental health services, the child patient and family should be reassured that the pediatrician or family practitioner will continue to be involved in their treatment. Such close liaison can help minimize any sense of abandonment or rejection they might experience.

With regard to the treatment of conversion symptoms, in particular, there is an old controversy among clinicians as to whether it is first necessary to remove the physical symptom and then conduct psychotherapy to deal with the underlying psychopathology, or whether the psychotherapeutic intervention will simultaneously address the symptom and its causes. Various procedures used for removing the symptom include suggestion (Proctor, 1958; Rock, 1971), encouragement (Gold, 1965), and chemical abreaction through the use of medications such as amobarbital (Laybourne & Churchill, 1972). More recent perspectives do not recommend withholding psychotherapy until the symptom is removed. Rather, clinicians now suggest helping the patient and family recognize that the symptom is not life-threatening in order to reduce their anxiety, and thereby make them more open to other treatments (Kellner, 1986; Maisami & Freeman, 1987; Schulman, 1988).

An important goal of any intervention with children and adolescents experiencing somatoform symptoms and disorders is to encourage their return to normal activities and to discourage "sick role" behaviors such as missing school, staying in bed, and avoiding friends. This rehabilitative approach involves a reframing of the child's symptoms and has two important features. First, it emphasizes that patients do not need to wait until their symptom(s) have improved for them to engage in their normal academic and social activities. This teaches them that they can keep going even when they are experiencing symptoms and discomfort. Patients with pseudoneurologic symptoms, particularly motor problems, are sometimes encouraged to do prescribed exercises or to see a physical therapist who can assist them with gradually returning to normal functioning (Dubowitz & Hersov, 1976) and with giving up their symptom while also "saving face" (Bolton & Cohen, 1986).

Second, this approach shifts the responsibility for "cure" from the physician to the patient; that is, the child changes from being a passive recipient of care to becoming an active collaborator in his or her recovery. Rather than looking for attention and rewards for sick role behaviors, the child seeks reinforcement and praise for his or her efforts at overcoming the symptoms and persevering in spite of them.

Another method sometimes used to reduce sick role behaviors is to arrange regular appointments with the physician independent of the child's physical condition. This provides children and their parents with opportunities to meet with their doctor without the child having to be symptomatic. In addition, the physician can use these appointments to reassess whether any medical conditions have developed that could account for their somatoform symptoms.

One additional complication in the treatment of children and adolescents with somatoform disorders is that not only does the child patient need to be convinced of the role of psychological factors, but typically the parents also need to be persuaded. There is often a shared belief among family members of the medical origins of the child's symptoms. Parents often are the primary reinforcers of the child's sick role behaviors. Therefore, interventions need to target the beliefs and behaviors of parents as well as the children.

Family perspectives about psychosomatic conditions (Minuchin et al., 1975, 1978; Mullins & Olson, 1990) suggest that the child's somatic symptoms serve a function within the family system. Family therapists argue that interventions should not focus on the identified child's symptoms because that distracts the family from the more important family processes that are maintaining the symptom. Minuchin and colleagues recommend that family therapy targets the enmeshment, parental overprotection, and conflict avoidance that often characterize these families. Thus, the basic principles for treating somatoform disorders include acknowledging the patient's physical symptoms while at the same time explaining to both the child and parents the possible contribution of psychological factors to the onset and maintenance of the child's symptoms. A multidisciplinary approach that involves collaboration between the physician and mental health workers is recommended. A primary goal of any intervention is the minimization of sick role behaviors and encouragement of a return to normal activities as soon as possible, although for some children this may need to be a gradual process.

5.25.11 TREATMENT

5.25.11.1 Psychosocial

Psychosocial approaches to the treatment of somatoform disorders in children and adolescents have generally included behavioral and cognitive techniques, psychodynamic psychotherapy, and group and family therapies. The particular technique used depends on the specific symptoms and disorder. Relaxation training (Larsson, 1992; Larsson & Mellin, 1988), hypnosis (Elkins & Carter, 1986), and biofeedback (Klonoff & Moore, 1986; Mizes, 1985) have been used to reduce tension associated with headaches and other pains. Cognitive interventions teach self-monitoring and coping strategies (Sanders, Shepherd, Cleghorn, & Woolford, 1994). Behavioral methods are used to reinforce mastery over symptoms and to reduce secondary gain associated with sick role behaviors (Delameter, Rosenbloom, Conners, & Hertweck, 1983; Mizes, 1985). Psychodynamic approaches aim to help children with conversion disorders to gain insight into unconscious conflicts and to identify how psychological factors can influence the maintenance of symptoms (Goodyer & Taylor, 1985). Some form of parent training, family education, or family therapy can be used to apprise parents of their possible role in the onset and maintenance of their child's somatic symptoms and to improve communication among family members (Mullins & Olson, 1990). For those children with somatoform disorders who are shy, unassertive, and have difficulty expressing negative emotions, interventions that also improve self-esteem, promote assertiveness, and train in emotion expression and regulation techniques can be helpful (Nemzer, 1996).

Reattribution techniques that involve simply making the link for the child and parents between the occurrence of a stressor and the onset of symptoms can sometimes lead to symptom improvement. When such insight is followed by targeted problem-solving such as making appropriate environmental and behavioral changes, symptom reduction may happen rapidly (Wilkinson & Mynors-Wallis, 1994). For example, interventions such as changing a child's classroom or having a conference with the teacher to address the child's specific concerns can eliminate somatic symptoms being used to avoid school.

Although there are many interesting case studies in the literature using a variety of psychosocial approaches for the treatment of specific patients (e.g., Andrasik, Burke, Attanasio, & Rosenblum, 1985; Delameter et al., 1983; Elkins & Carter, 1986; Linton, 1986; Miller & Kratochwill, 1979), there are relatively few controlled trials for the treatment of somatoform disorders in children. These studies have targeted specific somatic complaints, particularly recurrent abdominal pain (Finney, Lemanek, Cataldo, Katz, & Fuqua, 1989; Sanders et al., 1989, 1994) and headaches (Larsson & Mellin, 1988; McGrath et al., 1988; Osterhaus et al., 1993).

Finney and colleagues (Edwards, Finney, & Bonner, 1991; Finney et al., 1989) have examined the efficacy of using several different techniques including self-monitoring, limited parent attention, relaxation training, increased dietary fiber, and required school attendance. Finney et al. found that a group of 16 children who received a brief multicomponent targeted intervention comprising all of these methods had improved pain symptoms and decreased school absences compared to the untreated comparison group ($n = 16$). In addition, the treated group had significantly decreased medical care utilization.

Sanders and colleagues (Sanders et al., 1989, 1994) have conducted two studies examining the efficacy of cognitive-behavioral treatment of recurrent abdominal pain in children. In the first study (Sanders et al., 1989), the treatment program consisted of differential reinforcement of well behavior, cognitive coping skills training, and various generalization enhancement procedures. Although both the treatment and control groups showed a reduction in pain symptoms, the cognitive-behavioral treatment group had a more rapid improvement that generalized to the school setting, and a larger proportion of the treated children were completely pain-free at the three month follow-up.

Their second study (Sanders et al., 1994) compared the efficacy of a cognitive-behavioral family intervention (CBFI) with standard pediatric care (SPC) in 44 children with recurrent abdominal pain aged 7–14 years. Again, children in both treatment conditions showed improvements on pain intensity and pain behavior. The children in the CBFI group, however, also had a higher rate of complete elimination of pain, lower levels of relapse, and lower levels of interference with their activities. Thus, these studies show that some form of intervention typically leads to symptom improvement, although the more extensive treatments have broader and possibly longer-lasting effects on symptoms and functioning.

Efficacy of specific treatments for headaches in children and adolescents has been mixed. Relaxation training has been found to be superior to attention placebo control for the treatment of tension headaches (Larsson & Mellin, 1988) and migraines in adolescents (Larsson, 1992). Osterhaus et al. (1993) found that a combined treatment consisting of relaxation training, temperature biofeedback, and cognitive techniques reduced headache frequency and duration, although not intensity, compared with a waiting list control. Osterhaus et al. suggested that an increase in the ability to relax and a decrease in anxiety contributed to improvement. Helm-Hylkema, Orlebek, Enting, Thijssen, and Ree (1990) used the same training program as that of Osterhaus et al. but in a clinical setting and found that 90% of their young adolescent patients showed significant improvement. McGrath et al. (1988), however, reported that among adolescents attending a pediatric neurology clinic for migraines, relaxation was not found to be more effective than a "placebo" discussion of psychological topics. It could be that their control condition, which involved receiving reassurance and assistance, and attending to psychological factors, was sufficiently effective in reducing migraines among these adolescents. Thus, relaxation procedures show some promise in reducing headaches in children and adolescents, although further research needs to be conducted exploring what might be the effective ingredients of "control" interventions. Although much has been written about how to deal therapeutically with conversion disorders (e.g., Hodgman, 1995; Maisami & Freeman, 1987), there have been few controlled treatment studies in either adults or children. Adult patients who received psychotherapy for pseudoseizures have been found to be significantly improved compared to those who did not undergo treatment (Lesser, Lueders, & Dinner, 1983; Meierkord, Will, Fish, & Shorvon, 1991).

5.25.11.2 Medical Interventions

Treating somatoform disorders with medical interventions such as pharmacology and hospitalization is a complex issue because of the message it sends to the child and family. One concern about using medication is that this might perpetuate the patients' beliefs about the organic etiology of their symptoms. Indeed, some physicians resort to prescribing placebos to avoid the patient's anger about not receiving medical treatment. This could have the negative effect, however, of perpetuating the child's view of him or herself as sickly and in need of medical intervention.

On the other hand, providing some medical intervention helps to validate the reality of patients' physical distress and thereby might increase their willingness to accept other forms of treatment as well; that is, if the physician does not simply dismiss patients' symptoms as being "all in their head," then patients might be more open to a multimodal approach. Moreover, some medical interventions, even if they are over-the-counter remedies, can at least alleviate some of the physical discomfort they are experiencing.

In addition, if a child with a somatoform disorder is experiencing comorbid symptoms such as anxiety or depression, then psychopharmacological treatment aimed at reducing these symptoms might be warranted. If children's somatic symptoms are reduced as a function of psychotropic medication, then this might help to convince them and their parents that psychological factors may be contributing to their physical problems. In adults, antidepressants have been found to reduce somatic symptoms in depressed patients, and anxiolytic medications appear to alleviate somatic symptoms in patients diagnosed with anxiety disorders, such as panic (Kellner, 1991). There have been no controlled treatment studies of the use of antidepressants or antianxiety medications for children or adolescents with somatoform disorders with comorbid emotional disorders. There is some evidence of the efficacy of selective serotonin reuptake inhibitors (SSRIs) for the treatment of adolescent depression (Emslie, Rush, & Weinberg, in press) and pediatric obsessive compulsive disorder (Riddle et al., 1992), and for the use of medications in the treatment of childhood anxiety disorders (Allen, Leonard, & Swedo, 1995). Given the high rates of anxiety and depressive disorders among children with some forms of recurrent somatic complaints (e.g., Garber et al., 1990; Hodges et al., 1985a; 1985b), such a treatment study might be informative.

Sometimes the patient's lack of improvement with medical treatment can assist in the diagnosis of a somatoform disorder; that is, if the symptoms do not get better with a medication known to be effective for a particular medical condition, then it is less likely that the patient has that condition. Thus, prescribing medication can serve as a diagnostic test as well as a form of treatment.

Are there any conditions under which hospitalization of children with somatoform disorders would be warranted? If the use of outpatient psychotherapy and pharmacological interventions have been found to be ineffective, then pediatric or psychiatric hospitalization may be appropriate. Inpatient hospitalization has been suggested when there is diagnostic uncertainty or marked functional impairment, such as persistent school refusal (Goodyer, 1981; Leslie, 1988). Such treatment can be accomplished best with a multidisciplinary team on a pediatric medical psychiatry inpatient unit (Campo & Raney, 1995). Hospitalization provides an opportunity for careful observation and control of environmental contingencies. Moreover, removal from the environmental conditions that might be producing or exacerbating the symptoms can be informative and therapeutic.

5.25.12 CONCLUSION AND FUTURE DIRECTIONS

The diagnostic criteria that define somatoform disorders have changed with each new edition of the *DSM*. The validity of these criteria for use with children still needs to be investigated. Epidemiological studies are needed that assess the full range of symptoms that comprise these disorders and that test the validity of different symptom cut-offs and combinations.

One of the real challenges for diagnosing somatoform disorders is the necessity of conducting comprehensive medical as well as psychiatric evaluations. Multidisciplinary teams that include medical and psychiatric staff are required for the assessment and treatment of patients with somatoform disorders. These evaluations should include information from multiple sources (i.e., children, parents, teachers) and should use multiple assessment methods including questionnaires, psychiatric interviews, observation, and amytal interviews when relevant. Similarly, interventions typically will require the cooperation of physicians and mental health specialists. Successful treatment is likely to involve individual therapy with the child as well as family therapy that addresses the system maintaining the child's symptoms.

Somatoform disorders are a heterogeneous category of loosely associated syndromes. They share the feature of physical symptoms that are not explained simply by a medical condition. It is likely that multiple factors comprising a biopsychosocial model contribute to the etiology of somatoform disorders. Moreover, it also is likely that a unique, although somewhat overlapping, set of processes underlie each disorder.

There also are age, sex, and cultural differences in somatic complaints and somatoform disorders that need to be studied further. How might the observed sex differences in the rates of somatoform disorder inform us about its etiology? Similarly, how are the different rates and patterns of somatic complaints in different cultures and subcultures explained?

Additional issues for future research concern the comorbidity of somatoform disorders with other internalizing problems. To what extent do other emotional disorders such as anxiety and depression underlie the somatic symptoms that comprise somatoform disorders? What is the extent of somatic symptoms in children with other emotional disorders (McCauley, Carlson, & Calderon, 1991)? How do children diagnosed with emotional disorders with and without somatic symptoms differ with regard to their prognosis, etiology, and treatment response?

Somatoform disorders are important because they drain society's economic and medical resources, strain the family environment, and hinder children's social and academic development. Further research is needed that addresses the assessment, etiology, prognosis, and treatment of each of the different types of somatoform disorders across the lifespan. Early interventions that target high-risk populations can help reduce the cost of these disorders to both individuals and society.

5.26.1 INTRODUCTION

Factitious disorder, simply put, is the intentional simulation of illness through a variety of false pretenses. This includes reporting exaggerated symptoms, fabricating laboratory results, and actually inducing symptoms through physical means such as ingestion of substances, injection, or suffocation. Factitious illnesses often result in numerous expensive and painful, not to mention unnecessary, laboratory tests, hospitalizations, and surgical procedures for the young "patient" before the charade is finally uncovered.

What is not so simple is the identification and understanding of this disorder, which poses serious challenges in differential diagnosis and effective treatment. Much better represented in the adult literature, often as "Munchausen syndrome," factitious disorder in youngsters is certainly known to occur, but has yet to be studied in any systematic manner. There is a very limited literature on factitious disorders in children *per se*, while there is an extensive literature of related disorders, diagnoses, and conditions which may provide intriguing clues to the etiology of this disorder. While this chapter will address factitious illness which involves a child or adolescent as the object of unnecessary medical attention, we will find that the perpetrator can actually be the child him or herself, the parent, the family unit, or a complex pathological collusion between parent and child. The relationships between these different yet similar presentations is still little understood, but poses intriguing clues for fiuture understanding of the development of the many forms of somatization and illness exaggeration throughout the lifespan.

5.26.2 FACTITIOUS DISORDERS

5.26.2.1 Phenomenology

Factitious illnesses have no doubt been observed for as long as there have been healers and physicians. Reports in the medical literature dating back to the early nineteenth century (Gavin, 1838; Jacobi, 1895) indicated a variety of falsely presented medical conditions such as factitious fevers. However, the most systematic and seminal discussion of fabricated illness dates back to the work of Asher (1951) writing in *Lancet*, who first coined the colorful name of "Munchausen's syndrome." This term was used to describe a perplexing type of patient who wandered far and wide seeking medical treatments and hospitalizations for nonexistent or self-induced illnesses. These patients were notorious for dramatic presentations, brief emergency room or surgical stays often ending in early detection and the flight of the patient to the next hospital or city. At the time, Asher reported that the three major organ system presentations involved abdominal, hemorrhagic, and neurologic symptoms. Since Asher's original paper, there have been hundreds of Munchausen syndrome papers in the adult medical literature elaborating on individual or sometimes a series of factitious illness cases involving all manner of factitious presentations, including fevers (Aduan, Fauci, Dale, Herzberg, & Wolff, 1979), rashes (Reich & Gottfried, 1983), and even psychiatric presentations (Hay, 1983; Phillips, Ward, & Ries, 1983; Pope, Jonas, & Jones, 1982).

5.26.2.1.1 Munchausen syndrome and factitious disorder

The disorder described by Asher was named after a fascinating man and equally colorful character, the Baron Karl Friedrich Hieronymus von Munchausen, an eighteenth century cavalry officer and mercenary who was renowned for telling elaborate tales of his imaginary adventures, chronicled by his friend Rudolf Erich Raspe (Sakula, 1978). Both men and women from all walks of life have been described as exhibiting the "Munchausen" disorder. The mean age of onset of the disorder is said to be most commonly in the patient's early twenties (Raymond, 1987) and perhaps up to half the cases may begin in adolescence (Plassmann, 1994a). The literature reports that men tend to predominate in the most chronic, "wandering" form of Munchausen syndrome (at a ratio of 2:1) in which multiple physicians, towns, and hospitals are caught up in the patient's relentless charade. Women have been found to predominate (at a 3:1 ratio) in the less dramatic forms of factitious disorder, more likely in episodic or less elaborate impostures (Eisendrath, 1996). However, the methods of self-abuse and the range of false symptoms and organ systems involved have been remarkably extensive and dramatic, confined neither to a single gender, ethnicity, socioeconomic, or age group. Many of these patients are involved in the medical, nursing, or health care professions (Plassmann, 1994b).

Within the factitious disorder (FD) literature are a handful of reports on children or adolescents discovered to have manufactured their own symptoms and illnesses. The reports of young children include a four year old feigning seizures (Croft & Jervis, 1989), a nine, ten, and fourteen year old creating skin lesions (Lovejoy, Marcuse, & Landrigan, 1971; White, Pearson, & Coddington, 1966), several series of children between 11 and 17 years with factitious fevers (Aduan et al., 1979; Herzberg & Wolff, 1972; Wedel, 1971), preadolescents adulterating laboratory specimens (Abe, Shinozima, Okuno, Abe, & Ochi, 1984; Abrol, Heck, Gleckel, & Rosner, 1990), and factitious charges of sexual and physical abuse by a 12 year old (Feldman & Smith, 1996).

Factitious illnesses show increasing sophistication with age, and the adolescent literature includes a patient deliberately ingesting steroids (Witt & Ginsberg-Fellner, 1981), a patient scraping her skin and pouring nutritional supplements down the drain (Sanders, 1995), self-induced chronic joint inflammation and pain in a 15 year old (Paperny, Hicks, & Hammar, 1980), use of a wrist tourniquet for self-induced edema by a 15 year old (Rodriguez-Moreno, Ruiz-Martin, Mateo-Soria, Rozadilla, & Roig-Escofet, 1990), the injection of exogenous egg protein into the bladder (Tojo et al., 1990), and 15 hospitalizations for a wide variety of nonexistent illnesses by an adolescent (Raymond, 1987).

The vast majority of these reports have appeared in the medical rather than the psychiatric literature, with the resultant emphasis more on the unraveling of the medical puzzle than an explication of the etiology or family dynamics. As in the case of adult FDs, it is clear that these cases, particularly with more clever adolescent imposters, can stymie physicians for several years before being discovered as factitious (Abe et al., 1984; Paperny et al., 1980). They generally result in an expensive, destructive process of multiple hospitalizations, laboratory procedures, and surgeries before the fabrication is finally unmasked. The physical and psychological toll on the patient, and the professional/emotional toll on the physicians and the health care system can be enormous (Schreier & Libow, 1993a).

5.26.2.1.2 Factitious disorder by proxy

That the great majority of FDs in children is seen in adolescents is no doubt due to the fact that a certain basic level of medical sophistication is required to create and maintain believable symptoms capable of entrapping physicians successfully. Unfortunately, a substantial number of very young children are also, in fact, victims of fabricated illness—victims of Munchausen by proxy syndrome (MBPS), or factitious disorder by proxy (FDbP). First systematically described and named by British pediatrician Meadow (1977), MBPS involves the use of the child (or less commonly, another adult) as the proxy "patient." The parent or caregiver exaggerates symptoms, or actually induces illness in her child in order to maintain an ongoing relationship with doctors and hospitals (Schreier & Libow, 1993a). The most common methods of inducing illness include poisoning, suffocation, tampering with specimens or intravenous lines, skin adulturation, witholding medication, and false reporting of symptoms. The child manifests the factitious illness, but it is the parent/mother who carries the FDbP diagnosis.

There are currently several hundred cases of FDbP reported in the medical literature, with the vast majority of perpetrators being mothers (Levin & Sheridan, 1995; Schreier & Libow, 1993a) with complex societal and systemic reasons for this gender imbalance. These mothers have been classically described as highly devoted, seemingly very concerned, and medically sophisticated parents, although a subset of these parents have also been noted to be more hostile and demanding (Libow & Schreier, 1986). A review in 1987 by Rosenberg reported on 117 cases in the literature, and found that 24% of the mothers themselves had Munchausen syndrome or at least some elements of FD. Classically, the fathers or partners of the MBPS mother are described as distant, uninvolved, or emotionally disengaged from the family. The child victims can be of any age, gender, or birth order, and sometimes several children in one family are victimized serially or simultaneously. Child victims can be biological children, adoptive, or foster children, and often do not show any obvious signs of attachment problems or physical child abuse. The age of the child victims have ranged from as young as fetuses subjected to prenatal fabrication (Goodlin; 1985; Goss & McDougall, 1992), to infants (Light & Sheridan, 1990; Meadow, 1990), preschoolers (Guandolo, 1985) and latency age (Libow & Schreier, 1986; Palmer & Yoshimura, 1984) as well as adolescent victims (Katz, Mazer, & Litt, 1985). Generally it is the infants and toddlers who are subjected to the most active forms of physical symptom inductions such as suffocation and poisoning (McClure, Davis, Meadow, & Sibert, 1996), while the older children tend to be victims of what have been called the "milder" form of MBPS (Roth, 1990; Warner & Hathaway, 1984). "Doctor shopping" and symptom exaggeration, in which the parent does not actively induce symptoms herself, can also subject the child to unnecessary procedures and medications through exaggerated or false reporting of symptoms (Masterson, Dunworth, & Williams, 1988). Often older children have been noted to engage in either passive or active collusion in such fabrications, confirming their mother's reports to the physicians (Woolcott, Aceto, Rutt, Bloom, & Glick, 1982), failing to report falsehoods (Sanders, 1995), or even participating in inducing symptoms.

Factitious disorder by proxy differs in a number of ways from FD, although there are obvious areas of overlap. Often the "by proxy" deception takes longer to be revealed, because the mothers are more convincing imposters and the fabrications are more sophisticated (Schreier & Libow, 1993a). Some percentage of the proxy victims actually die from the abuse. Rosenberg (1987) calculated that number to be approximately 9% of cases, although that likely represents an overestimation due to the preponderance of more severe cases in the literature she reviewed. Because the proxy cases involve an innocent victim, the morbidity and mortality of the patients is even more distressing, as is the devastating impact of this abuse, once it is revealed, on the treating physicians who are drawn into unintentional participation in the abuse (Schreier & Libow, 1993a).

5.26.2.2 Diagnostic Features/Differential Diagnosis

5.26.2.2.1 Diagnosis of childhood factitious disorder

As in all forms of factitious illness, the first and most important issue in differential diagnosis is the ruling out of bona fide physical illness. No matter how obscure or elusive, the presence of a true medical illness which can account for the presenting symptoms negates the diagnosis of FD, unless the symptoms are exaggerated way out of proportion to what should reasonably be expected. Thus, physicians generally expend considerable effort in attempting to provide the most exhaustive medical workup possible for a patient with mysterious symptoms, including extensive laboratory tests, radiological procedures, biopsies, genetic studies, and hospital observations, and often institute treatments in the hope that responses to treatment might provide clues to diagnosis. In most cases the diagnosis of FD is the last possibility considered, when all else has been ruled out, and when the "illness" fails to fit any usual pattern of symptoms, is physiologically impossible, fails to respond in an expected way to common treatments, and provides other clues as to its inconsistency and its tendency to reoccur only when the patient is not being observed closely. The identification of factitious illness in younger children tends to be easier due to the lack of sophistication of the falsifications, but as with adults, can be greatly complicated when the patient has coexisting, bona fide medical problems such as asthma, or serious iatrogenic illness induced by efforts to treat the original "problem." Livingston (1992) reminds us that several organic disease states have

> vague, strange, and transient symptoms and are easily confused with somatization: systemic lupus, multiple sclerosis, juvenile rheumatoid arthritis, acute intermittent porphyria, partial complex seizures, and inflammatory bowel disease ... it may be that only the longitudinal picture will establish the diagnosis firmly but a reasonable clinical judgment about working diagnosis can often be reached by complete history from multiple sources, thorough mental status exam, a careful probe for the family history, personality patterns and comorbid difficulties known to be associated with somatoform disorders, and ancillary psychological exams for characteristic profiles and findings. (pp. 14–15)

DSM-IV (American Psychiatric Association, 1994) includes "Factitious Disorder" as an Axis I disorder involving three elements, including: (i) the intentional production of physical/psychological signs and symptoms; (ii) the motivation to assume the sick role; and (iii) the absence of external incentives for the behavior. It includes three subcodes based on whether the signs and symptoms are predominantly psychological, predominantly physical, or a combination of physical and psychological in nature. *ICD-9* (Stegman & Aaron, 1996) lists factitious disorders as subcategories of "Hysteria" under "Neurotic Disorders."

There are separate categories for factitious illness with psychological symptoms (300.16) and other and unspecified factitious illness (300.19) which includes factitious physical symptoms. There is a different category for "Munchausen syndrome" or chronic factitious illness with physical symptoms (301.51) in *ICD-9*, coded separately under the "Histrionic personality disorders."

Seemingly quite straightforward, the diagnosis of FD in adults as well as children and adolescents is complicated by its considerable overlap with a number of related disorders which also involve the presentation of physical or psychological symptoms which are unobservable, do not appear to have an organic basis, or have an element of conscious production, unconscious motivation, or secondary gain for the patient. Somatization disorder, malingering, conversion disorder, anxiety disorders, and mood disorders can all be confused with FD, and differential diagnosis is often a challenge. The three most critical variables in differentiating the phenomenon of FD are the following.

(i) *Motivation.* Patients who are motivated to produce factitious symptoms for obvious external gain, such as disability payments, avoidance of military service, or evasion of criminal prosecution, rather than less conscious needs as in FD, are identified as malingerers, a V-Code in *DSM-IV*. Identification of the possible material gain/motivation of the patient requires careful identification of the tangible impact of the patient role on the person's lifestyle, finances, and responsibilities. In the case of children, the differential diagnosis of malingering from somatization and factitious disorder is complicated by the fact that in all cases, the child's creation of illness symptoms is likely to result in reduced school attendance and considerably increased parental involvement. In these cases, a careful psychosocial and family systems evaluation will be critical in sorting out the likely motivation for assuming the sick role, and determining whether fully conscious as opposed to less conscious needs are being gratified. In the case of the FDs, it is proposed that assuming a dependent yet controlling role in relationship to the powerful and caregiving physician is the primary motivation. However, in reality there are often tangible gains for young FD patients—such as missing school or engendering parental sympathy—which can be identified as possible secondary incentives, but not the primary motivators of the behavior.

(ii) *Intentionality*. Probably the most difficult variable to assess in FD is the degree to which the exaggeration or falsification of symptoms is conscious and intentional. Elaborately orchestrated deceptions are much easier to identify as intentional than exaggerated symptom complaints. By definition, FD is intentional, although believed to be compulsively driven, and therefore not entirely under the control of the patient. Patients who present repeatedly with a range of nonexistent medical complaints involving multiple symptoms and organ systems, but who are *not* consciously exaggerating or falsifying symptoms, are diagnosed with somatization disorder. As in FD, somatization can be episodic or chronic, and can pose major difficulties for the physician attempting to treat questionable symptoms with no apparent organic basis. Conversion disorder is diagnosed in the case of more restricted symptoms related to identified stressors (e.g., abdominal pain or "paralysis" following an incest experience). As in factitious disorder, somatization can be episodic or chronic, and can pose major difficulties for the physician atempting to treat questionable symptoms with no apparent organic basis.

(iii) *Chronicity*. There is some confusion about the use of the term "Munchausen syndrome," as it is often used generically to refer to all forms of fabricated illness. In general, presentation of the patient with chronic false symptoms, and a lifestyle centered around repeated wandering from hospital to hospital seeking medical care is classically known as "Munchausen syndrome," while FD is not as chronic, and can involve even a single episode (Folks & Freeman, 1985; Nadelson, 1979).

Munchausen patients have also been described as having poorer employment histories and more antisocial traits (Carney, 1980; Folks & Freeman, 1985; Spiro, 1968). Clearly, the term FD is more appropriate for use with child patients by these criteria. While many authors use both terms interchangably to describe patients who produce their own symptoms, others have attempted to identify differences in the groups in terms of gender distribution (Feldman & Eisendrath, 1996; Folks & Freeman, 1985), age, and degree of compulsivity (Spiro, 1968). What remains unclear is whether more episodic FD is qualitatively different, or whether the episodic patient eventually becomes the chronic Munchausen patient, given sufficient success over time in the impostering of illness.

What becomes clear is that the differentiation of patient intentionality, motivation, and even frequency of fabrication are not always easy to gauge by the clinician making the diagnosis, suggesting there may be considerable lack of specificity in the actual use of these terms or in the disorders themselves. A number of clinicians have proposed the concept of a continuum or spectrum of related disorders including Aduan et al. (1979), Barsky (1992), Fink (1992), Folks and Freeman (1985), and Nadelson (1979). Cramer, Gershberg, and Stern (1971) remind us that "A volitional factor in the genesis of hysterical symptoms has long been recognized ... " as well as " ... unconscious factors in the genesis of malingering" (p. 576). A number of authors have pointed to the multiple difficulties in differentiating the various "dissimulating disorders" including Jonas and Pope (1985) who remind us that malingering, conversion disorders and FDs have several striking similarities. All typically begin in late adolescence or early adulthood, all appear to have a relatively chronic course, therapeutic approaches appear to be relatively ineffective for all, and the patients all appear to display a similar pattern of psychiatric diagnoses which include histrionic, antisocial, and borderline personality disorders. They even suggest there may be a gender bias in diagnosis, with women tending to receive somatization and conversion disorder diagnoses, while men may tend to be perceived as Munchausen or malingering patients.

Spiro (1968) agrees that hysterical and factitious symptomatology are not always mutually exclusive categories, and he describes a classic Munchausen patient who also suffered occasional conversion abdominal pain. Fink (1992) also points out that while somatization and FD appear to constitute separate entities at any one point in time, the categories may actually merge or overlap over time. That is, his study of 113 patients found that 18% of his "persistent somatizers" were discovered to have intentionally self-induced their diseases, lesions, or illnesses at least once or to have manipulated test results. "The number of patients who had produced factitious objective symptoms were probably underestimated as they were only registered if clear evidence was present" (p. 134). He suggests that we may tend to underdiagnose the number of patients with FD because clear evidence of deliberate fabrication is not always present, and it is so difficult to know whether symptoms are actually consciously produced.

It is possible that this clinician bias towards diagnosing somatization is even stronger when it comes to child patients, as it may be even more psychologically difficult for medical providers to suspect children of deliberate falsifications, and there is less extensive psychosocial history available for assessing possible motivation, intent, etc. Some authors have indicated awareness that some supposed child "somatizers" may in fact be intentionally producing their symptoms (Garralda, 1996; Sanders, 1995). There is often a broad definition of child somatization used in the literature, such as Campo and Fritsch's (1994) use of the term for "medically unexplained physical symptoms" (p. 1223). In the absence of any attention to the issues of motivation or conscious awareness, this broad use of the term "somatization" could easily encompass an unknown percentage of deliberately "ill" children. This remains an issue for which our definitions and diagnostic tools require further refinement.

5.26.2.2.2 Diagnosis of factitious disorder by proxy

DSM-IV (American Psychiatric Association, 1994) includes a second category of factitious disorder, called "Factitious Disorder Not Otherwise Specified." This is supposed to incorporate cases of FDbP, although FDbP itself is included in the *DSM-IV* Appendix as needing additional study and refinement. It is differentiated from the category of "Factitious Disorder" by its definition as "Intentional production or feigning of physical or psychological symptoms *in another person who is under the individual's care*." Thus, their definition would include the abuse of an elderly person, hospital patient, or another adult. As in FD, the diagnosis requires the motivation to assume the sick role by proxy, the absence of external incentives, and the condition that the behavior is not better accounted for by another mental disorder. Perpetrators may, and often do, also receive additional diagnoses of various personality, somatoform, or mood disorders where appropriate. There is no discrete psychiatric diagnostic category within *ICD-10* for FDbP.

As in FD, the parental behaviors seen in MBPS or FDbP first and foremost must be differentiated from those seen in response to bona fide physical illness. If the medical problem in question is, in fact, due to real physical illness, the diagnosis of FDbP is inaccurate. Krener and Adelman (1988) point out that there are some superficial similarities between the "pathogenic parents with Munchausen's syndrome by proxy and the parents of chronically ill children" (p. 946). They demonstrate that chronic illness itself may create some features of parental behavior commonly seen in FDbP parents, including extensive medical knowledge, an unusual focus on the child's bodily products, and "inseparable maternal devotion." While there are very few known cases of misdiagnosed FDbP, the potential dangers of wrongly accusing a parent of this form of child abuse and mental disorder are very sobering. One of the few known cases of a misdiagnosis of FDbP involved a mother who was jailed for the murder of her infant son, believed to have poisoned him with ethylene glycol (Chin & Breu, 1991). It was only the illness of a second child, while his mother was in jail and without access to this child, that alerted authorities to the misdiagnosis and eventually allowed for the discovery of the rare genetic disorder that had killed one child and made the other so ill. In the majority of cases, physicians are generally extremely cautious about making the diagnosis, often spending months or years, and sometimes hundreds of thousands of dollars in repeated tests and procedures before acknowledging that FDbP is the only possible explanation of a persistant medical puzzle (Schreier & Libow, 1993a).

What is often confusing to diagnosticians and physicians is that the behavior of the parent with FDbP seems to fall on a continuum that includes a range of both normal and abnormal parent behavior in relation to the health care system. Eminson and Postlewaite (1992) suggest there exists a range of "parents' desire to consult for their child's symptoms" which includes nine points along the spectrum with classical neglect at one extreme and classical MBPS (or FDbP) at the other. They propose that other points along the spectrum include parental carelessness, noncompliance, and "normal" responses to child's symptoms, progressing up the scale to anxious behaviors, exaggeration, and finally, invention of symptoms. It clearly requires patience, expertise, considerable time, and investigation of the family system and the presenting symptoms in order to differentiate the anxious parent, the somatizing parent, or the thought-disordered parent, from the parent with FDbP. As in FD, the central elements of the FDbP diagnosis once again revolve around a persistent search for treatment of an induced or exaggerated illness, the parent's conscious intent to deceive, and an unconscious motivation for a relationship with the medical system rather than more material secondary gain. As Meadow (1984) reminds us, "Unfortunately there is no sharp dividing line between deliberate falsification (malingering for conscious gain) and abnormal illness behaviour in which there is unconscious gain (hysterical behaviour). The end result for the child is the same, and can be both cruel and dangerous, regardless of the origin of the mother's behaviour" (p. 156).

Even more complex is the difficulty of diagnostically sorting out the puzzle of FDs in the case of older children. Beyond the age of toddlerhood, many if not most child victims of FDbP are believed to have at least some level of awareness of the exaggeration or induction of their symptoms by their parents, and some are known to actively participate in verifying "the story" in the case of "doctor shopping" (Woollcott et al. 1982) or actually inducing their symptoms. In fact, the one study of adults victimized by FDbP as children (Libow, 1995) found that many of the victims were fully aware of the deception, but too intimidated or unsure of how to free themselves from this abuse to speak up. Sanders (1995) presents what she calls a "continuum of collusion with Munchausen by proxy syndrome" which includes the categories of the naive child, passive acceptance, active participation, and active harm.

Many studies indicate that some child and adolescent victims of FDbP actively collude in the deceptions with their parents in an effort to protect or maintain a relationship with their parents or continue the "only life they know" (Schreier & Libow, 1993a). What becomes very difficult at this point is to sort out the appropriateness of using the FD diagnosis for the child actively participating in the fabrication as opposed to the status of FDbP victim. It becomes particularly difficult to differentiate the child's possible beliefs and motivations regarding the illness—for example, should the colluding child be considered a somatizer if a parent is responsible for directing the deliberate falsifications?

Other concerns have been raised about the diagnosis of FDbP including those of Morley (1995) and Baldwin (1996) who are concerned about the nonspecificity of many of the criteria for this diagnosis, and the inclusion of other forms of fabrication beyond active induction of illness including false symptom reporting and exaggeration of genuine illness; some feel this may result in overinclusion of too many anxious or overdramatizing parents. Fisher and Mitchell (1995) take issue with the concept of FDbP as a "syndrome" as they feel that perpetrators manifest a wide range of psychopathology and presentations, with many "psychological, psychiatric, and environmental pathways leading to a behaviour of fabricating illness in a child" (p. 533).

5.26.2.3 Prevalence

5.26.2.3.1 Factitious disorder prevalence

Solid, systematic prevalence data on FD does not really exist, due to the significant challenges in assessment of intentionality and motivation, and the surreptitious nature of this disorder (Taylor & Hyler, 1993). Furthermore, since diagnostic criteria for factitious and somatoform conditions have been under revision over the years, epidemiological studies are difficult to conduct (Krener, 1994).

There is actually more prevalence-related literature available on FD in adults, with factitious fever one of the most studied single symptoms. Knockaert, Vanneste, Vanneste, and Bobbaers (1992) found that 3.5% of 199 cases of fever of unknown origin seen at one hospital over a 10 year period were factitious. Their review of four other studies of unexplained fever revealed rates of factitious fever ranging from 2.5% to 4.5%. Herzberg and Wolff (1972) reported that 13 patients in a sample of 200 (or 6.5%) at the National Institutes of Health (NIH) were considered to have factitious fever. A study of fever at Stanford University (Rumans & Vosti, 1978) found that 2.2% of some 500 cases were factitious in origin. Aduan et al. (1979) reported on another study of fever of unknown origin at NIH, involving 343 patients, which identified 9% as factitious (this group included 10 children under 18 years old).

A study that spanned a broader spectrum (Reich & Gottfried, 1983) surveyed 10 years of records on the medical and surgical wards of a Boston hospital, and identified 41 patients with a variety of documented FDs (they do not report prevalence figures) including some adolescents. The most common and serious disorders were infections produced by injection or insertion of contaminants through or into the skin surfaces. They concluded that "factitious disorders are far from rare on hospital wards, at least in tertiary hospitals" (p. 245). Pope et al. (1982) reported on a study of 219 psychiatric patients, which found that 6.4% probably had factitious psychotic symptoms. They suggest that clinicians should be especially suspicious of histrionic and borderline patients who experience "brief dips into psychosis."

A study of 282 patients with heavy utilization of in-patient admissions in Denmark (Fink, 1992) indicated that approximately 20% of the patients had no physical illness or disorder that could adequately explain their multiple admissions. They conducted several comparisons of what they called "persistant somatizers" and "nonsomatizers" and found that 18% of the "persistant somatizers" (defined as having more than six unexplained admissions) had at least one known admission for a factitious illness. It is at least clear that FD in adolescents and adults is not a trivial problem. Unfortunately, similar data does not exist for FD in children. But there are indications that it may not be rare in children, given observations of the high rates of somatization in children (Garralda, 1996) and of conversion symptoms in adolescents (Friedman, 1973) as well as Livingston's (1992) observation that "Mendacious presentations of physical disorder, currently classified either as factitious disorder or as malingering, are also far from rare among young people" (p. 13).

5.26.2.3.2 Factitious disorder by proxy prevalence

The collection of relevant prevalence data on MBPS or FDbP is also confounded by the absence of any national registry on this form of child abuse, and the likelihood that significant numbers of these cases are never identified or are misdiagnosed (Holborow, 1985; Schreier & Libow, 1993b). However, as with FD in adults, there are some intriguing studies which provide suggestive data that can be extrapolated to the larger population.

Some studies have been done on specific types of specialized medical problems in an effort to determine the possible rates of factitious presentations. Light and Sheridan (1990) surveyed 125 infant apnea programs across the United States and reported that 54 cases (2.7 per 1000) were believed to involve parents inducing apnea. Warner and Hathaway (1984) found that about 5% of some 300 parents seen in their allergy clinic appeared to have a "parental obsession" with food allergies that appeared to constitute FDbP. McClure, Davis, Meadow, and Sibert (1996) studied all cases in Ireland in a two year period involving a child protection conference, and identified 55 cases of MBPS out of 128 cases. They reported a combined incidence of MBPS, poisoning, and suffocation of 0.5 per 100 000 children, but admitted that these were likely an underestimate because cases were only identifed if they were reported and a child protection conference was called. They also found large regional differences in patterns of reporting, which also suggested differences in the ability of reporters to effectively recognize or pursue child abuse cases. Similar differences in rates of identified cases were reported by Schreier and Libow (1993b) who surveyed all 880 pediatric neurologists and 388 gastroenterologists in the United States in 1991 to collate data on their MBPS cases. With return rates of 21.8% and 32.4% respectively, these subspecialists reported a total of 273 confirmed cases of FDbP. As in the McClure study, the significant variability in the number of cases seen by different reporters suggests that there are great differences in the familiarity with and ability to identify these cases and that perhaps a significant number are missed entirely.

5.26.2.4 Etiology

5.26.2.4.1 Origins of factitious disorders

Since there are so few papers on FD in children and adolescents, and even fewer discussions of etiology in childhood cases, the adult literature provides the most useful directions for theory building. However, it must be acknowledged from the outset that all discussions of etiology and treatment are handicapped by the fact that these patients are notoriously resistant to psychotherapeutic intervention, and often flee from the hospital before mental health professionals even have an opportunity to obtain an adequate psychosocial history. However, case studies and theoretical discussions of this disorder provide intriguing ideas about the origins of fabricated illness.

One of the earliest discussions of etiology of chronic FD is offered by Spiro (1968) who points out the parallels between FD and imposture, including the patients' histories of early neglect and deprivation, a desire for mastery over early traumatic experience, and a discrepancy between the patient's self-image and the ego-ideal. He suggests that the patient repeatedly seeks mastery over his/her early experiences of pain and fear by his/her demanding behavior in the guise of being a medical patient, which is coupled with revenge and hostility.

Cramer, Gershberg, and Stern (1971) present four adult Munchausen cases and offer similar observations on their object relationships. In particular, they point to their patients' early experiences with physicians as authority figures who likely began as idealized figures but gradually generated disappointment and eventually, feelings of revenge. They point to their patients' intense wish for closeness and a state of dependency on the physician, paradoxically mixed with feelings of rivalry and desire for control. They describe serious ego disturbances, which are manifested in unstable identifications, primitive defenses and a surge of sadistic wishes against their abandoning parent(s), as represented by the physician. Plassmann (1994a) makes a distinction between the (chronic) Munchausen patient and the (episodic) FD patient, suggesting that the Munchausen patients have a history of infantile-acquired attachment to physicians who are omnipotent, idealized figures, while FD patients have a less idealized relationship with physicians and more of an early fear/interest in their own bodies. He found that many of his FD patients (54%) had been subjected to physical abuse in childhood, which is eventually transformed, often in adolescence, into the patient's destructiveness towards his own body.

Eisendrath (1996) also suggests that childhood experiences of physical or sexual abuse may be significant causes of later FD, generating feelings of guilt in response to sexual excitement or anger. The FD is hypothesized as a possible vehicle for the abuse to be masochistically re-enacted, with the physician serving as the abusing or depriving parent. The use of deception may create a sense of power and superiority in relation to the caregiver. He also suggests that FD may serve as a means for the patient to achieve a greater sense of control and mastery, needed perhaps as a result of childhood traumatic illness. Alternatively, he also proposes a more behavioral theory that FD may have its origins in childhood reinforcement for illness behaviors by eliciting parental attention, support and caring, and an escape from childhood responsibilities. Spiro (1968) describes just such a case in which the earliest memories of a chronic FD patient involved his happy recall of winning his parents' attention during a hospitalization at age four years and a series of later medical complications.

Several authors also highlight the crucial issue of how children learn illness behaviors within the family milieu. Barsky (1992) offers the concept of "amplification" to explain the process by which people learn to interpret their bodily sensations as intense and noxious. While sidestepping the issue of etiology, he suggests the three key elements in this process as bodily hypervigilence to unpleasant bodily sensations, a tendency to focus on weak or infrequent sensations, and the tendency to appraise these sensations as abnormal. The possible contribution of parents in this process is unspecified.

Krener (1994) points more directly to the ways within the family context that children may learn how to experience and communicate their emotional and physical states. "Parents in psychosomatic families may adduce physical symptoms as an explanation of their child's state, behavior, or response, just as they use them to explain their own feelings. Children are more vulnerable than adults to this influence and to developing somatic representations of emotional states, which, like other coping and mastery skills acquired in childhood, involves learning, suggestion, and psychological compliance" (p. 419). It is not difficult to imagine that a child living with a somatizing or even a fabricating parent might come to rely increasingly on somatized explanations and a patient role, eventually coming to participate more actively in convincing physicians to believe in a nonexistent illness.

Unfortunately, the rather limited literature on childhood and adolescent FD is even more restricted in the number of papers which present any detailed early history, parental or family psychosocial background that could shed light on the various theories of the genesis of FD. Many focus almost entirely on the medical presentation (Abe et al., 1984; Abrol et al., 1990; Lovejoy et al., 1971; Paperny et al., 1980; Wedel, 1971). However, a few papers on child FD point to an intriguing link between child and parent preoccupation with illness.

A careful reading of the child FD literature describing family background suggests that some of the mothers play a pivotal role in encouraging or even teaching illness fabrication to the child (Stankler, 1977). Sneed and Bell (1976) describe a 10-year-old boy who presented with abdominal pain, bloody urine, and "kidney stones" which were later found to be ordinary pebbles. The article described the mother as actively involved in the fabrication, reporting "blood" on the stones and describing her own passage of kidney stones years earlier; she "tended to exaggerate physical problems and illnesses for herself, the siblings, and the patient" (p. 127). Her son was described as passive and compliant, and almost completely dependent upon his mother.

Herzberg and Wolff's (1972) report on six children presenting with factitious fever of unknown origin at the NIH also included some fascinating data about the mothers' presentations. The children ranged from 11 to 17 years of age, and were all described as "good, compliant, serious, but lonely" children. The authors felt that four of the mothers had "very troubling chronic illnesses of their own" which appeared highly inconsistent with observations or history. Several of the mothers were actually noted to be involved in the fraudulent reporting of the childrens' temperature elevations; one mother persistently pictured her daughter as suffering from leukemia despite negative findings! The authors observed that the children appeared to be recruited to help the parents with their own inner conflicts. The "sick" children were noted to enjoy increased attention from their parents that might not have otherwise been available as well as a break from demanding schoolwork. Interestingly, two of the six children aspired to be medical doctors!

One of the most elaborate factitious illness presentations (Gilbert, Pierse, & Mitchell, 1987) involved a 13-year-old boy seen over six months time at an otolaryngology clinic with recurrent otalgia, bloody discharge from the ear, and chronic mastoiditis with a cerebrospinal fluid leak. Just as the child was facing a temporal craniotomy, forensic analysis identified the "ear fluid" as beetroot juice, and the boy admitted to placing the material in his ear. A retrospective review of this boy's three-year medical history revealed a long series of nonspecific complaints resulting in 28 outpatient visits, 15 specialist consultations, 4 surgical procedures, 2 endoscopies, 52 blood tests, and 20 x rays. The medical staff wondered if the boy's mother had been coaching him in his fabrications since "It seemed unlikely that a 13-year-old would have the medical sophistication to simulate a cerebrospinal fluid leak or comprehend the significance such a sign would have for the attending surgeons" (p. 232). Also suggestive of FDbP involvement was the mother's domineering style and devoted attendance at bedside, previous health care employment, and efforts to have her son immediately discharged when confronted with the fabrication. Many years earlier, Steinbeck (1961) reported on a 19-year-old girl simulating massive vaginal hemorrhage and hematemesis through concealing blood; her mother was also later found to be an accomplice in her deceptions.

Similar reports of maternal involvement are found in a case described by Croft and Jervis (1989) of a four-year-old, seen over a year's time, with 35 emergency room visits for repeated "fits," trembling, and a "paralyzed" arm which were all being feigned by the child. The boy had a history since age two which included "cyanosis" and episodes of shaking and unconsciousness at age three. The child eventually described how his mother had taught him to simulate his epileptic "fits" by shaking, falling out of his chair, and flickering his eyes, and he reported being rewarded by his mother with food and drink when he performed for her. His "fits" stopped after five months in foster care. Unfortunately, there is no psychosocial history provided for the mother herself.

Perhaps one of the most unusual descriptions of FD collaboration between parent and "child"—in this case a 25-year-old daughter and her 59-year-old mother—is offered by Janofsky (1986). Both mother and daughter were hospitalized together with similar complaints of fevers, nausea, headaches, weakness, etc., and both had long medical histories engaging over 100 physicians. When psychiatric consultations were recommended, both mother and daughter fled the hospital against medical advice. The author suggests that this case of chronic FD in the mother, and a budding FD daughter, would meet the classic criteria of "folie a deux," or even "folie a famille," given the husband's willing participation as well as the physician son's facilitation of the process!

So it is apparent that FD behavior can involve overt modeling, direct coaching of the child, active collaboration on the part of the parent, and behavioral reinforcement for the child's participation. Many of these parents would no doubt fit the definition of MBPS parents. What becomes increasingly difficult to differentiate diagnostically, and an area of increasingly blurred boundaries, is the distinction between the FDbP parent with a "colluding child," and a childhood FD with a cooperative parent. These cases suggest that at least some percentage of childhood FD cases have their origins in the child's direct exposure to the coaching of a parent with factitious disorder or factitious disorder by proxy.

5.26.2.4.2 Origins of factitious disorder by proxy

As in adult FD, theories of etiology for FDbP are limited by the difficulties in obtaining accurate and detailed psychosocial histories from these reluctant and often court-ordered patients. Spiro's (1968) and Cramer et al.'s (1971) theories of the etiology of FD have many parallels to the origins of FDbP, particularly in terms of histories of early neglect and deprivation, and the mother's enactment of an idealizing/hostile attachment to the physician. The description of a MBPS mother's early background by Wood, Fowlkes, Holden and Castro (1989) is fairly typical. They describe a childhood of early deprivation and humiliation, resulting in marked insecurity, deep resentment of authority figures, and inability to meet the patient's needs through the usual means. In the case of FDbP, the infant or child is hypothesized to serve as a type of "fetish object" in the mother's "perverse" relationship which is focused on reducing anxiety by controlling the physician/authority figure and warding off abandonment (Schreier & Libow, 1993a). While many FDbP mothers appear to have some history of paternal loss or abandonment, others have different, less dramatic types of loss, as in a loss of self- or parental esteem through neglect or traumatic illness, or loss of a father's interest. Interestingly, many mothers with FDbP seem to re-enact these unsatisfying relationships with men in later life by marrying aloof and distant husbands who are often absent and uninvolved in their wives' lives and the children's "illnesses." Somehow, these fathers are allowed to remain aloof and uninvolved by our physicians and health care institutions, who seem to accept their absence or fail to insist on their participation.

In fact, social factors which allow for distortions and inequities in gender roles also appear to play their part in the etiology of FDbP, in that many women grow up in a societal context in which they feel desperately unrecognized, and have few outlets for a sense of power and importance outside of their caretaking roles as mothers. Ironically, the role of "devoted mother" of a chronically ill child is one of the few traditional, socially sanctioned roles for women which also allows them access to an exciting and powerful world of hospitals and health care (Schreier & Libow, 1993a). Others place some responsibility on our medical systems (Donald & Jureidini, 1996; Fialkov, 1984) for the development of MBPS, or on the "medicalization of childhood, clinical and social iatrogenesis and the creation of a society obsessed with health and its concomitant illness" (Baldwin, 1996, p. 161). But while there are interesting theories about these different influences, we know little about the relative contributions of childhood neglect, character disorders, sociocultural influences, and family systems dysfunctions in their eventual evolution into the destructive and often life-threatening behavior of medical abuse.

5.26.2.5 Developmental Course of Factitious Disorders

While addressing a somewhat different population, the literature on the course of somatization disorder in children offers useful directions for our thinking about the course of FD in children. Livingston's (1992) excellent review of somatization in childhood and adolescence found that it tends to have a progressive or chronic course similar to that found in adults. Furthermore, he reported that somatoform syndromes in children that do not yet constitute full somatization disorder may do so over time, and childhood somatizers are unlikely to reach adulthood without developing other kinds of serious psychopathology. His general conclusions were that abdominal and other pains develop first in the early school-age population, followed by neurologic or conversion symptoms during later elementary or adolescent years. The number of symptoms then appears to peak in the female patient's early 20s and decline gradually, although for men the peak appears to be several decades later. Livingston (1993) has also found that children of adults with somatization disorder almost universally develop psychiatric disorders.

Factitious disorder is not ordinarily seen until at least early adolescence in most children due to lack of medical sophistication (Aduan et al., 1979). Children much younger than 12 are very likely to have an active parental ally either engineering or at least encouraging the deception, while adolescent patients might be expected to have some earlier history of medical problems or somatization. Reich and Gottfried's (1983) study of FD provides some data on the early histories of their patients. All of their patients who self-induced their infections began in adolescence although many were not identified until later in adulthood. All of them apparently showed an early interest in medical matters and hypochondriacal preoccupations, although none had histories of serious childhood diseases. Paperny et al. (1980) described the case of a late adolescent whose history of factitious illness spanned the five years between 15 and 20 years of age. He endured 23 hospitalizations and 13 surgical procedures, while functioning as an "excellent student" who worked for a year in an orthopedist's office. An even longer history was available on a 28-year-old FD patient described by Sale and Kalucy (1980) who found that this patient lived with a mother who was ill during most of her childhood, and had infrequent and probably genuine medical visits until age 12. From age 12 through 17 she made frequent use of the gynecology clinic with abdominal pain complaints and engaged in many struggles with her physicians; she manifested features of adult FD from age 17 onwards. Reich, Lazarus, Kelly, & Rogers (1977) provide detailed early history on a 15-year-old boy who simulated an enterovesicular fistula by contaminating his urine with feces and food by retrograde injection of substances into his bladder. They found that his early history included moderately severe asthma, multiple allergies, surgery at age two for hypospadias, and a prolonged episode of unexplained fever at age 12. The authors concluded that the patient's factitious behavior was due to a hypochondriacal anxiety state about his urogenital system, but did not address the question of familial or maternal contributions to his medical history or to his surprising level of medical sophistication at a young age.

Little can be said about the long-term developmental outcome of FD beyond the fact that the illness behavior is likely to continue into adulthood, and may or may not become chronic. All that is available is retrospective data, as neither the young patients actually diagnosed with this disorder nor those whose diagnoses are missed can be studied prospectively.

There is somewhat better developmental data available on child victims of FDbP. It is clear that some percentage of infants subjected to the most severe forms of this abuse will die as a result of suffocation and poisoning (Meadow, 1990) and some will have long-term physical damage (Rosenberg, 1987). Certainly there is known psychological damage to children who endure medical fabrications at the hands of their parents (Bools, Neale, & Meadow, 1993; Roth, 1990). McGuire and Feldman (1989) not only found many severe adverse psychological effects of FDbP on their child victims, but also found that some of their young patients developed conversion symptoms or were starting to manifest FDs themselves.

A fascinating case of a 9 year old being contaminated by human fecal matter by her mother was presented by Palmer and Yoshimura (1984). Their examination of the mother-perpetrator found that the mother herself had an extensive history of FD in adolescence, adult FD later in life (as well as a job as a nurse practitioner), and eventually FDbP using her own daughter! Investigations even earlier into this mother's history revealed that she herself had had an extensive childhood medical history which included an unexplained fracture as an infant, failure to thrive, episodic vomiting, frequent injections for minor complaints, and several questionable procedures done at an early age. The possibility in some families of a multigenerational cycle of MBPS alternating with FD is a fascinating and disturbing one.

A retrospective study of 10 adults who reported themselves as victims of childhood FDbP (Libow, 1995), some as much as 40 years earlier, noted that they experienced serious developmental and emotional problems throughout the lifespan including growth failure, school problems, poor self-esteem, difficulty in relationships, depression, and difficulty separating fantasy from reality. Remarkably, some even reported that their mothers sporadically attempted to continue to abuse them even into adulthood! Thus, unless it is actively stopped by physicians who discover the deception, FDbP may run a chronic course, although the most active forms of induction in the child's early years tend to give way to more indirect forms of illness exaggeration, often gradually drawing the child or adolescent into passive or active cooperation, with increasing risk of physical harm and psychological morbidity.

5.26.3 CONCEPTUALIZATION AND CLINICAL FORMULATION

5.26.3.1 Multimodal Assessment

5.26.3.1.1 The medical puzzle

There are many obstacles to the accurate identification of FDs, starting with the deception on the part of the patient and the lack of an accurate history, the patient's cooperation, or a meaningful medical picture. The episodic and emergency nature of many of the illnesses, the involvement of multiple physicians and institutions, and the difficulty for the physician of even contemplating deception on the part of a youngster or a seemingly exemplary parent adds to the challenge of identifying medical deception in a timely way before great harm is done (Guandolo, 1985). Schreier and Libow (1993a) also detail many of the ways in which the susceptible physician is drawn into the patient's imposture and is sometimes blinded to what otherwise appears to be rather obvious and blatant falsification. Often it is the close observation by nursing or ward staff of peculiar family interactions and inappropriate affect on the part of the patient or parent that finally alerts medical staff to take a very different perspective on the intractable medical problem.

In any case, the first step in the assessment of either FD or FDbP is a multidisciplinary team meeting of all involved physicians, social workers, psychologists, specialists, consultants, nurses, and other team members, in order to pool data, share observations, identify discrepancies, and develop a plan to further pursue investigation of possible deception. While it is often not possible to find direct evidence of fabrication, this is most desirable as it allows for a clear and unambiguous response from the health care team, and possible legal action in the case of child abuse. In the case of childhood factitious disorder, direct evidence can be gathered through such ruses as checking serial numbers on thermometers to identify planted ones (Herzberg & Wolff, 1972), and comparing urine specimens collected under observed and unobserved conditions (Meadow, 1977). In many pediatric hospitals surreptitious video surveillance is now being used under carefully controlled conditions for collecting evidence of medical abuse. Parents have been caught on camera in the act of suffocating as well as poisoning their young children (Samuels, McClaughlin, Jacobson, Poets, & Southall, 1992).

However, in many cases the deception can only be inferred through a careful process of eliminating all other possible medical explanations for the child's symptoms. The peculiar, sporadic, physiologically impossible, or unresponsive nature of the symptoms may be the major clues available to the alert physician. There are a number of cases of young children in which a direct confrontation has resulted in the child's confession of the fabrication (Abe et al., 1984; Croft & Jervis, 1989; Lovejoy et al., 1971), but in the case of older FD patients or

FDbP parents, there is often flight, denial, and lack of cooperation with treatment. In the case of child victims of serious medical abuse, the separation of the child from the parent often offers the most important diagnostic verification of the fabrication, as the child's condition rapidly improves and symptoms disappear in the absence of the suspected perpetrator. However, there are often legal and ethical obstacles to the separation of suspected victims from their mothers, and even the evidence of child's improvement in the mother's absence is often challenged in court.

5.26.3.1.2 Psychological assessment

If the patient is amenable to a psychological interview, the psychologist can make a significant contribution to the understanding of the patient's dynamics and treatment. Particularly important for these patients is the gathering of a detailed and thorough history, both psychosocial and medical, on the child patient as well as siblings and parents. Nothing can be taken at face value, and all history, particularly of previous illness and dramatic events (such as deaths, fires, car accidents), should be verified through other sources including detailed medical records from other institutions. Many therapists and examiners make the mistake of failing to question and verify *all* important background information provided by FD patients, which only further complicates the understanding of the etiology, dynamics, and personal issues of the patient.

Questions about the patient's motivation, chronicity, and conscious intent to deceive can be fruitfully addressed in psychological interviews and family observations. In particular, an exploration of the patient's relationship to his/her physicians, and the day-to-day impact of the "illness" role on the patient's life may help clarify the function of the deception and the needs being met. An exploration of the patient's current family life, relationships with parents, siblings, and significant others can be useful in clarifying important influences, reinforcers, and models for the sick role. Children are likely to be more candid and less deceptive in their presentation, as they may be less aware of the implications of what they reveal.

Psychological testing instruments can contribute to a comprehensive picture of the patient's functioning, particularly when the examiner uses instruments that are less susceptible to conscious deception. The dissimulation scales of the Minnesota Multiphasic Personality Inventory (MMPI-II) and projective tests such as the Rorschach and the Thematic Apperception Test have been particularly useful in this regard. For example, Aduan et al., (1979) reported psychological test results for five adult FD cases and elicited themes of inhibited expression of anger, affective deprivation, faulty concepts of identity, and difficulty separating self from others. They described FD patients as generally suffering from underlying severe personality disorder " ... characterized by hostility, dependency, imposture and poor impulse control with self-destructive acting-out" (p. 238). A review of psychological test data available on adult FD patients (Schreier & Libow, 1993a) found that identity confusion, and sexual and aggressive impulse control issues were significant; defenses included acting out, projection, somatization, and denial. Only limited and mostly case study test data has been available on child FD patients.

There has also been limited psychological test data presented for child victims of FDbP. Ojeda-Castro (1995) recommends thorough developmental and psychological assessments of child victims to assess for developmental delays due to chronic illness, multiple hospitalizations, or deprived environments. Other important concerns for these children are dependency issues, separation anxiety, issues of bodily integrity, and issues of trust and attachment to caregivers. However, it must be noted that the diagnosis of FD or FDbP cannot be made on the basis of a psychological evaluation alone, as there is no uniform profile of such patients, and many manage to present themselves as fairly "normal."

5.26.3.2 Treatment Formulation

The treatment process begins with the open acknowledgment directly to the patient that his/her caregivers suspect deception. The first (and often the last) phase of treatment is confrontation with the patient and family, when the physicians and health care team reveal their findings and directly address the factitious illness. This confrontation is essentially unavoidable in the case of fabricated illness being actively treated by medical staff, although milder forms of symptom exaggeration can sometimes be addressed more indirectly to help the patient "save face" while referring him/her on to treatment. In the case of illness exaggeration, Richtsmeier and Waters (1984) suggest it is not very useful to directly challenge a "family myth" or explain what is "really going on" if the family is unable to hear it. Instead they recommend developing trust, with the physician continuing to meet with the patient and gradually exploring psychological issues, hopefully eventually resulting in the acceptance of psychological referrals.

The approach selected for the confrontation of the blatantly fabricating patient is critical to the possibility of forming an alliance with the family and maintaining their accessibility for psychotherapeutic treatment. Without a successful confrontation, there is no possibility of ongoing follow-up. A successful confrontation does not necessarily require an admission by the patient, but should at least conclude with an agreement to seek psychological services. Unfortunately, it may not be possible, even with the most carefully chosen team and therapeutic approach, to successfully join with all FD or FDbP patients. In fact, it is very common for cases described in elaborate medical detail in the literature to conclude with the unfortunate fact that the patient was confronted, fled the facility, and was never heard from again (e.g., Rodriguez-Moreno et al., 1990; Witt & Ginsberg-Fellner, 1981). Many of the younger FD patients described in the literature apparently do confess fairly readily to their fabrications when confronted (Abe et al., 1984; Abrol et al., 1990; Croft & Jervis, 1989; Lovejoy et al., 1971; White et al., 1966), which is much less likely in older patients.

Given that denial and flight are common responses to confrontation of adolescents and FDbP perpetrators, practitioners have outlined a number of suggestions for approaching the confrontation to maximize success. Wedel (1971) recommends a "therapeutic confrontation" in which a trusted, supportive social worker is included in the team meeting, which should convey concern and acceptance to decrease the patient's sense of shame and anxiety. Many authors address the need to avoid a punitive, rejecting stance on the part of the medical team, as these feelings are common reactions of health care providers duped into active collusion with unnecessary treatment. Hollender and Hersh (1970) developed an approach which includes the pairing of a confronting physician and a supportive psychiatrist to maximize their success. It is important for the team to include at least one psychiatrist or psychologist, and for an emergency plan to be ready in case the patient becomes actively suicidal (Schreier & Libow, 1993a). If the patient agrees to psychotherapeutic treatment, it is recommended that the contract include the patient's agreement to confine all his/her medical treatment to a single facility or group of physicians familiar with the disorder, to help contain the behavior. In the case of FDbP, this restriction is often built directly into court orders for parent–child reunification.

If the confrontation is successful and the patient remains accessible, the task of treatment remains formidable. Some authors recommend initial psychiatric hospitalization for long-term in-patient care (Plassmann, 1994b) if that is feasible. However, it is much more common for out-patient psychotherapy to be the primary mode of treatment. A combination of behavioral and psychodynamic approaches have been recommended, with an emphasis on exploring the nature of the patient's historical relationships with physicians and authority figures and developing insight into the use of illness in daily life. There is little consensus on successful treatment approaches to the FD patient, and the full range of psychotherapeutic approaches, from behavioral to psychodynamic to family systems, have been utilized, with limited success.

5.26.4 TREATMENT

5.26.4.1 Psychosocial Treatments

5.26.4.1.1 Psychotherapy for factitious disorder

There is virtually no treatment literature available describing psychotherapy for children or adolescents who fabricate illness, and this is especially surprising compared with the considerably more extensive literature on child somatization disorder and its treatment (Campo & Fritsch, 1994; Garralda, 1996). This is partially due to the fact that many of the children fabricating illness make early admissions when confronted. Some of the reports on FD report that younger children, in particular, do not seem to repeat this behavior once confronted, although it is unlikely that many of these patients have been followed prospectively in any systematic way. Suggestions about therapy for these children that have been made, not surprisingly, include the need for involvement of the family system, including Herzberg and Wolff's (1972) recommendation for parental couples therapy to avoid sabotaging the child's treatment. White et al. (1966) suggest that the clinician needs to allay parental concerns about illness, and help the parent(s) minimize secondary gains by insisting the child resume full activity and school responsibilities.

Once again the adult FD literature is more informative on treatment and includes several descriptions of individual therapies. A German psychiatrist, Plassmann (1994c), reviewed approximately 350 papers on the treatment of FD and found that the "vast majority of psychotherapies undertaken do not go beyond an initial phase consisting of several psychiatric interviews" (p. 96). He found that the major issues in successful treatment involved the problem of how to confront the patient, selection of the appropriate setting (in- or out-patient), the establishment of a positive working relationship, and countertransference issues. His review found that the most frequently used therapeutic methods were analytically oriented therapy, hypnosis, psychoanalysis, and group therapy. His paper also described his own psychodynamic treatment of 12 patients, mostly in in-patient or long-term out-patient therapy, which utilized an "approaching phase," an "introjection phase," and a "separation phase."

Most other authors report on only single cases or very small samples. For example, Schoenfeld, Margolin, and Baum (1987) described the long-term treatment of a young adult patient with a combination of dynamic and supportive therapy. They described the value of working with a nurturing female therapist as a "corrective experience," and they used the patient's children to generate treatment motivation. Stone (1977) treated a young woman in an in-patient psychiatric unit, although she checked herself out against medical advice Two male adult FD patients were treated on an in-patient unit in Ireland with a variety of "communication techniques" and the fostering of a highly dependent relationship with the therapist (O'Shea & McGennis, 1982). Fras (1978) described a very supportive, cautious approach to psychotherapy which avoided challenging the patient's denial and resistance too vigorously. A supportive four-month treatment of a patient was described by Jamieson, McKee, and Roback (1979) focused on reinforcing reality-testing, although the patient was apparently still producing symptoms on follow-up. Schreier and Libow (1993a) and Eisendrath and Feder (1996) also report a variety of other approaches that have been used with FD patients including aversive therapy, biofeedback, paradoxical approaches, systems interventions, and behavioral contingencies.

It should be noted that countertransference issues for the therapist working with FD patients can be a significant obstacle to joining with the patient and establishing a positive working relationship. Schreier and Libow (1993a) present two detailed cases narrated directly by the therapists who treated the MBPS mothers which highlighted the therapists' own difficulties even recognizing their patients' manipulations. The patients' efforts at impostering the role of "cooperative patient" apparently sabotaged the therapeutic efforts of even these motivated and well-intentioned therapists.

5.26.4.1.2 Psychotherapy for factitious disorder by proxy

As in the treatment of FD, there is no single specific treatment for the parent or adult with FDbP, but instead a variety of psychotherapeutic techniques and approaches, assuming the patient is still amenable for treatment after the initial confrontation. Since few mothers with this disorder immediately acknowledge the problem, most enter therapy guardedly, or under court order. One of the few successful treatment cases was described by Nicol and Eccles (1985) who detailed a one-year treatment of a mother, focused on uncovering and interpreting her fantasies related to her ambivalent relationship with her father and her family culture of exaggerating illness. Lansky and Erickson (1974) described couples work in a family in which the child was being poisoned by the mother with caustic agents and medication.

Palmer and Yoshimura (1984) provided unusually detailed psychosocial histories for both a mother and her child victim of FDbP, and suggested that treatment of such children should be intensive and reality-focused, emphasizing the "gradual removal of pathologic defense mechanisms and on expanding the child's understanding of his or her state of physical health, of the parent's role in the creation of the illness, and of the parent's psychological state" (pp. 507–508). They described the issues of bodily integrity, feelings of helplessness and overly close mother–child interactions that emerged during a play therapy evaluation of their nine-year-old patient.

Suggestions for treatment of very young child victims of factitious illness are offered by Ojeda-Castro (1995), who described a play therapy approach for helping victims resolve issues such as the violation of basic trust, attachment problems, the "incongruous mother image," and the distorted self-image. The sessions begin with thorough cognitive and developmental evaluations of the child, move into regressive play therapy, and gradually work towards joint sessions with the mother, if reunification is anticipated.

One of the more unique, specific approaches to treating children involved in FDbP is offered by Sanders (1995). She proposes a narrative approach to working with families in which children collude in the exaggeration of illness. The goal of the therapist is to challenge the family's "story of illness" and help them develop an "alternative story" and means of coping. Involvement of the parents is considered very important to the success of treatment, and this approach seems mainly useful for more cooperative families.

5.26.4.1.3 Efficacy of psychosocial treatment

Unfortunately the difficulty of assessing successful outcome is probably greater in FDs than in most other psychiatric disorders, due to the ever-present risk of deception and the difficulty of accurately verifying the cessation of chronic or compulsive repetition of the behavior. Furthermore, the simple absence of the originally falsified medical symptom(s) may not represent the best outcome measure. As Campo and Fritsch (1994) remind us, "Outcome for patients with troubling somatization early in life may not be as positive when functional and psychiatric status is evaluated at follow-up, as opposed to the presence or absence of the original physical symptom" (p. 1231). That is, a child who stops fabricating an illness after being confronted or even treated in therapy is not necessarily psychologically healthy upon termination of this behavior. Furthermore, one has to questions some "positive" outcomes that have been reported for factitious disorder patients, such as the patient described by Fras (1978) who stopped inducing diabetic problems and started a nursing career, and another (Schoenfeld et al., 1987) who moved from factitious illness to work as a paramedic!

Certain factors do seem to point to better prognosis. The less chronic, more episodic FD patients seem to have a better response to both confrontation and therapy than Munchausen patients. Folks and Freeman (1985) remind us that patients with underlying mood or anxiety disorders have a better prognosis for treatment than those with coexisting personality disorders. We must treat any psychopathology such as depression, conversion symptoms or psychosis, often before the FD itself can be addressed. At the same time, factitious psychological disorders can coexist with factitious physical disorders and must also be ruled out before treatment is derailed.

Above and beyond all of these cautions, it must be noted that the efficacy of treatment approaches for both FD and FDbP is questionable. A handful of papers describe limited success on a case study basis. Even Plassmann's (1994c) report of an intensive treatment study involving 24 patients found that only half the patients even accepted the offer of treatment, and only three of the patients showed a disappearance of factitious symptomatology and marked changes in social competence as a result of treatment.

Reports on the effectiveness of treating mothers with MBPS are equally cautionary. Schreier and Libow's (1993a) review of the literature reports very limited success in the treatment of this disorder, as do McGuire and Feldman (1989), who note little effect of treatment on mothers' insight or medical abuse behavior. They also point out that even if the illness fabrications cease, the child victim may continue to manifest significant psychological problems and may eventually begin to seek inappropriate medical care him or herself. However, the increase in awareness, identification, and treatment of FD cases is beginning to offer some hope for the development of more effective treatments.

5.26.4.2 Pharmacological Treatments

5.26.4.2.1 Uses of pharmacotherapy

There are only a handful of reports on the use of pharmacotherapy in the treatment of FDs, and they generally involve treatment of the patient's concurrent mood or anxiety disorders. It has been suggested by Earle and Folks (1986) that antipsychotic medication can be useful for the treatment of brief psychotic episodes in FD patients, just as antidepressants may be appropriate for depressed patients. One apparently successful example in the literature is Schoenfeld et al.'s (1987) use of antianxiety and antidepressant medication in conjunction with dynamic therapy for an FD patient. One of the only known uses of pharmacological agents directly for treatment of FD is described by McDonald et al. (1979) who used sodium amytal ("truth serum") interviews to gather more accurate information from their patients. Unfortunately, they found that it had no real value for treatment itself.

5.26.4.2.2 Efficacy of pharmacotherapy

There is no known pharmacotherapy treatment designed specifically for FD or FDbp, although the use of psychoactive medication may be useful in establishing and maintaining the treatment relationship and treating coexisting psychiatric disorders in these patients.

5.26.5 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

For a variety of reasons already outlined, the study of FD in children and adolescents is in its very early stages. To begin with, untold numbers of cases of fabricating children and adolescents are likely being misidentified under the broader category of somatizers when their deliberate deceptions are not detected. Thus, there has been a limited pool of actual cases for study and it is likely that only the most blatant or persistant fabrications have been identified. An area ripe for more study is the clarification of the relationship between somatization, malingering, and FD in children, to determine if these represent qualitatively different diagnostic entities or whether there is considerable overlap. Further research may clarify whether there is even a developmental progression from one to the next. Furthermore, we need to better understand the similarities and differences between young people who consciously exaggerate their symptoms and those who actively induce illness; these distinctions are equally important to understand in the mothers who use illness exaggeration and those who engage in the active induction of illness in their children. The establishment of better diagnostic tools for assessing intent, motivation, and conscious deception, and a better program of education for physicians in recognizing the problem would be extremely helpful in collecting better data about these interesting and troubling cases of children who deliberately induce their own illnesses.

Beyond diagnostic considerations, it is clear that our understanding of the etiology and treatment of these disorders is also in its infancy. Earlier and more intensive involvement of pediatric psychologists in the assessment of FD patients, perhaps even before some of the families are confronted and lost to follow-up, would allow for the collection of more detailed psychosocial histories that should include not only the child's detailed medical, developmental, and social history, but the medical and psychosocial histories of mother, father, and all siblings. The intriguing hints in the literature of possible multigenerational replication of FD and FDbP in families can only be fruitfully explored through examination of the family systems and backgrounds of as many family members as possible. In particular, the possible role of mothers with FDbP raising children who themselves later become active fabricators of illness is a fascinating one in our understanding of FD and its genesis in young adults. Further, it suggests that research into the ways that older children may learn to either collude with, or resist, the efforts of a fabricating parent can point directions to effective treatment approaches for victims of MBPS.

One of the suggestions that has been discussed in child abuse and child protection circles is that of developing some type of national registry of FDbP cases, so that better data can be collected on the prevalence, psychosocial histories, and successful and unsuccessful treatment approaches to these cases. Psychological test data is beginning to be collected by individual clinicans working with FDbP parents and by-proxy patients, which, if systematically collected and shared, might help develop profiles useful for clinicians in identifying FD cases. Nation-wide registries might also save our health care systems and child protective services considerable resources, and prevent continued harm to vulnerable children by allowing earlier identification and follow-up of chronic, itinerant FD patients.

5.26.6 SUMMARY

Physicians and clinicians have been sharing their experiences and observations about FDs in the literature for several decades. These simulated illnesses, intentionally exaggerated or induced by the youngster and/or the parent, are often medically treated for long periods of time before finally being discovered as factitious. Physicians are often drawn into believing in these deceptions for many complex reasons, and can unintentionally cause considerable harm to the child through unnecessary treatments, procedures, hospitalizations and the fostering of the child's career as an invalid. While the discovery of fabrications by preadolescent children is generally fairly rapid and tends to result in confession and cessation of the deception, the treatment of factitious illness in adolescents and adults and of factitious illness by proxy is often a difficult, frustrating process complicated by widespread confusion about the diagnosis, and lack of systematic data on etiology and treatment of these disorders. There may be considerably more cases of FD in our health care systems than are commonly recognized, and there appear to be family systems which perpetuate the process of misusing medical resources to meet complex psychological needs, resulting in multiple generations of family somatizers or fabricators. The development of a better research database on family histories, psychological test findings and responses to different treatment approaches could help reduce the serious physical and psychological damage resulting from these forms of self-induced illness, and perhaps prevent some children from progressing to lifetime careers of medical abuse.

5.27.1 INTRODUCTION

Childhood-onset schizophrenia and adolescent-onset schizophrenia are among the most devastating of mental disorders to afflict the young. Fortunately, the incidence of schizophrenia in childhood and early adolescence is quite rare with the onset of schizophrenia typically occurring during late adolescence and early adulthood. In current clinical research and practice, the diagnostic criteria for schizophrenia are the same for children, adolescents, and adults, thereby allowing for developmental effects on the presentation and expression of symptoms. Schizophrenic illness has been identified in children as young as three years of age (Russell, Bott, & Sammons, 1989), although psychotic symptoms do not usually appear or are not detected reliably until a child is at least six or seven years of age (Russell, 1994; Werry, 1996). Schizophrenia in children and adolescents, sometimes referred to as very-early-onset and early-onset schizophrenia, respectively (Werry, 1996), are often treated as distinct disorders although there are conflicting reports about the nature of the differences between the two forms of the illness (R. F. Asarnow & J. R. Asarnow, 1994).

Some of the earliest observations of childhood- and adolescent-onset schizophrenia date back to Kraepelin's (1883/1915) description of dementia praecox, a form of mental deterioration that involves disturbances of thought and that can occur even in children. Upon observing such symptoms in a group of children, De Sanctis (1906/1973) described the disorder as *dementia praecocissima*. Bleuler (1911/1950) subsequently introduced the term *schizophrenia* to refer to the same condition in children and adults, as identical diagnostic criteria were being used to categorize both groups. By the 1930s, however, all children with profound mental disturbances, including autism and other psychoses, were placed in a general category that was labeled "childhood schizophrenia" (Fish & Ritvo, 1979). This tradition persisted with *DSM-II* (American Psychiatric Association, 1968) and *ICD-8* (World Health Organization, 1967–1969). However, with the introduction of *DSM-III* (American Psychiatric Association, 1980) and *ICD-9* (World Health Organization, 1978), the field returned to the practice of using the same diagnostic criteria for identifying schizophrenia regardless of age. Given the considerable diagnostic heterogeneity that characterized the broad category of childhood schizophrenia from the 1930s until the 1970s, it can be difficult, if not impossible at times, to meaningfully interpret the earlier literature.

The material covered in the present chapter relies on *DSM-III* through *DSM-IV* (American Psychiatric Association, 1994), *ICD-9* (World Health Organization, 1978), and *ICD-10* (World Health Organization, 1992) diagnostic criteria. By necessity, the primary emphasis of this chapter will be on schizophrenia that has been diagnosed before the age of 12 as early adolescent-onset schizophrenia has received relatively less attention in the clinical research literature to date. It should be noted that some variability exists between clinical research sites with regard to the maximum age allowed for receiving a diagnosis of childhood-onset schizophrenia. The National Institute of Mental Health project on childhood-onset schizophrenia, for instance, does not accept patients with an onset of psychosis beyond the age of 12 while the UCLA Childhood-Onset Schizophrenia Research Program has raised the maximum age from 11 to 14 years. Across sites, schizophrenia in childhood is defined by age and not by physical development because there are considerable individual differences in the age at onset of puberty (Werry, McClellan, Andrews, & Ham, 1994).

5.27.2 SCHIZOPHRENIA AND OTHER PSYCHOTIC DISORDERS

5.27.2.1 Phenomenology

Relying upon more recent diagnostic criteria, there have been reasonably consistent findings across studies on the clinical presentation of schizophrenia in children. Moreover, many of the same qualitative symptoms which are found in children can be seen in adult patients diagnosed with schizophrenia. This is not a complete surprise as the same diagnostic criteria are being applied to children and adults, although the possibility remains that there are distinct developmental differences in the expression of schizophrenia (J. R. Asarnow, 1994). It is noteworthy that any similarity in symptomatology has been obtained despite the inherent difficulty in ascertaining complex, internal symptoms in young children and with recognition of the need to distinguish between clinical symptoms, such as delusions, and normal experiences in childhood, such as vivid fantasies (J. R. Asarnow, 1994; Russell, 1994). In the following discussion, some examples of psychotic symptoms in children are provided; additional examples of symptom expression in preadolescence can be found in Russell (1994).

The most common presenting symptom for children, as with adults, is auditory hallucinations. As shown in Table 1, auditory hallucinations have been observed in approximately 80–100% of cases. Command hallucinations, which are hallucinations that involve telling an individual what to do, are perhaps the most frequent and have been noted in over 60% of children with a schizophrenic disorder (McKenna et al., 1994; Russell et al., 1989). Oftentimes, children report that the commands are negative or violent in nature (e.g., "kick the furniture," "hit your mother," "kill the goldfish"). Other auditory hallucinations involve voices that are conversing with one another (e.g., two stuffed animals speaking with one another), are maintaining a running commentary on the child's thoughts or behaviors (e.g., "It was nice that you helped your brother today"), are making persecutory statements (e.g., calling the child names), or are of a religious nature (e.g., the voice of God or the devil calling the child by name).

Visual hallucinations also appear to occur with considerable frequency and have been reported in approximately 40% or more of children diagnosed with schizophrenia, as shown in Table 1. Some visual perceptions may be reported as accessible only to the child (e.g., "The magician does not want anyone else to see him"), whereas other images are assumed

Table 1 Comparison of studies reporting on clinical symptoms in children with schizophrenia.

			Hallucinations

[a] Subjects ranged in age from 12 to 16 years when screened for participation in the research study but the onset of psychosis was before age 12. [b] Schizophrenia was diagnosed before the age of 12. [c] The total sample includes children with clinical diagnoses of childhood schizophrenia, psychotic illness with schizophrenic features, and schizophrenia of childhood onset. Upon reclassification with *DSM-III* criteria, 14 of the 42 children were diagnosed with schizophrenia; the remainder generally appeared to exhibit schizoid disorder. [d] Approximate estimate of age, derived from the mean and standard deviation provided in the report.

to be visible to anyone present ("Can't you see? The branches are turning into snakes and they are going to get us").

Occurring far less frequently, by contrast, are tactile hallucinations (e.g., "I can feel bugs crawling on my legs") and olfactory hallucinations (e.g., "There's a stinky smell that makes me want to throw up"). As can be seen in Table 1, these hallucinations are typically observed in less than one-third of schizophrenic children. There is some evidence to suggest that non-auditory hallucinations may only occur in those children who experience auditory hallucinations (Kolvin et al., 1971; Russell et al., 1989).

As with adults, delusions are also quite common and have been found to occur in 55–100% of children with a schizophrenic disorder (see Table 1). The content of their delusions is varied and might include themes that are persecutory (e.g., someone is trying to harm the child), somatic (e.g., "My arms grow longer every time I go in the swimming pool"), grandiose (e.g., "I have the powers to decide who lives and who dies"), referential (e.g., the rotating emblem at a gas station is sending secret messages to the child), religious (e.g., "I'm not really a boy, I'm an angel that God sent to be on earth"), or bizarre (e.g., a child believes that he is a soccer ball) in nature. With increased age, hallucinations and delusions become more complex and elaborate, and the content reflects the developmental level of the patient. Themes of animals and monsters, for instance, are more prevalent among younger children, whereas sexual themes appear to be less common (Russell et al., 1989).

Another manifestation of schizophrenia is disorganized thinking or formal thought disorder. As shown in Table 1, thought disorder appears to be present in the majority of children diagnosed with schizophrenia and typically has been observed in 80–100% of cases. Signs of thought disorder include loose associations (e.g., "I am 10-years-old. My pen ran out of ink this morning"), illogical thinking ("I hate peanut butter but I love to eat it all the time"), incoherence ("The day to raindrops go"), and poverty of content of speech ("It does. Uh huh. Yes, does"). Obtaining reliable estimates of formal thought disorder in children can be very difficult, however, in view of developmental constraints on cognitive, linguistic, and practical social skills (e.g., Caplan, 1994; Russell, 1994; Werry et al., 1994), which may account for differences in reported rates between studies. Russell et al. (1989), for example, found that only 40% of their cases demonstrated formal thought disorder.

Inappropriate or flat affect are other common symptoms of schizophrenia and typically have been found in over 70% of children with a schizophrenic disorder (see Table 1). Schizophrenic patients may exhibit inappropriate or uncontrollable emotions, such as laughing at a sad story, responding irritably for no apparent reason, or fluctuating rapidly between emotions. Alternatively, children diagnosed with schizophrenia may show no facial expression and speak in a monotone voice.

Grossly disorganized behavior in schizophrenia can include unpredictable agitation (e.g., unprovoked shouting), extreme silliness, and difficulties with such goal-directed behaviors as maintaining personal hygiene. In children diagnosed with schizophrenia, grossly disorganized behavior has been found to varying degrees. McKenna et al. (1994) noted disorganized behavior in 84% of their sample, whereas Russell et al. (1989) detected it in only 40% of their cases. Green, Padron-Gayol, Hardesty, and Bassiri (1992) observed that either grossly disorganized or catatonic behavior was apparent in 32% of their childhood-onset patients. Catatonic motor behaviors involve psychomotor disturbances, ranging from motoric immobility to excited, excessive activity. In general, catatonic behaviors appear to be rare among children. McKenna et al. (1994) reported the highest rate at 37% and Russell (1994) did not find any cases of catatonic behaviors; other studies made no mention of catatonia, suggesting that it was rare or nonexistent in their samples.

Although suicidal ideation or suicide attempts are often present in adults with schizophrenia, rates of their occurrence in children have not been routinely reported in the literature. In a hospitalized sample of 21 childhood-onset schizophrenics, J. R. Asarnow, Tompson, and Goldstein (1994) observed evidence of suicidality in 76% of cases. The authors note that the rate of suicidality in their inpatient sample may be higher than in other samples as suicidal behavior can often precipitate hospitalization.

As Russell (1994) notes, some young children may not experience their psychotic symptoms as being particularly distressing or unusual. Instead, these symptoms may be perceived as indistinguishable from normal experience given their insidious and early onset. As the psychotic symptoms become more intrusive and interfere with attention, however, children may be more likely to become disturbed or frightened and will then describe their symptoms to parents or others. Parents and others who are close to the child initially may not recognize that a child is experiencing hallucinations and may, instead, attribute the child's behavior to daydreaming.

Documentation of the phenomenology of schizophrenic disorder in early adolescence has been relatively sparse in terms of the current number of studies available. Nonetheless, as shown in Table 2, the studies that do report on symptom patterns in adolescent-onset schizophrenia find considerable similarity in the relative proportion of symptom characteristics as compared with those observed in childhood-onset cases. The rates of symptoms noted by Remschmidt, Martin, Schulz, Gutenbrunner, and Fleischhaker (1991) and by Werry, McClellan, and Chard (1991) are somewhat lower than those obtained in children diagnosed with schizophrenia but this may be due in part to methodological differences in ascertaining symptom patterns. In the studies by McKenna et al. (1994), Russell et al. (1989) and Spencer and Campbell (1994), rates for psychotic symptoms were determined through interviews with the children and their families. Green et al. (1992) relied on clinical records, but noted that their charts received extensive documentation as it was understood that they would be reviewed for research purposes. In both studies of adolescents, symptoms were ascertained from reviews of hospital records although Werry et al. also attempted to subsequently interview patients and their families. It is possible, therefore, that reliance upon archival data could account for lower rates of psychotic symptomatology in adolescents than that observed in studies of childhood-onset schizophrenia.

While the constellation of symptoms appears to be similar across children, adolescents, and adults with schizophrenia, considerable heterogeneity exists in symptomatology across patients. To help delineate particular symptom patterns, the concept of positive and negative symptoms has been introduced in the clinical research literature on adults with schizophrenia. The more florid or bizarre symptoms, such as hallucinations and delusions, constitute positive symptoms, whereas deficient or absent behaviors, such as inappropriate affect, unchanging or flat facial expression and minimal speech, are considered negative symptoms. More recently, the concept of "deficit state" has been introduced to focus upon primary and enduring negative symptoms (Carpenter, Heinrichs, & Wagman, 1988). In adult schizophrenic patients, negative symptoms tend to be present early in the illness, are less responsive to treatment than positive symptoms, and are relatively stable over time (Arndt, Andreasen, Flaum, Miller, & Nopoulus, 1995). A predominant pattern of negative symptoms has also been related to poor outcome (e.g., Breier, Schreiber, Dyer, & Pickar, 1991), although Pogue-Geile and Harrow (1985) point out that the association may be due to the persistence of poor social and occupational functioning.

The distinction between positive and negative symptoms has been applied less frequently to children and adolescents with schizophrenia. Studies in the 1990s have determined that the positive and negative symptom patterns are present in children and adolescents, much as they are in adults (e.g., Maziade et al., 1996; Remschmidt et al., 1991; Remschmidt, Schulz, Martin, Warnke, & Trott, 1994). In examining the course of these two symptom clusters in childhood- and adolescent-onset schizophrenia, Remschmidt et al. (1994) found some suggestion that negative symptoms may occur over a longer period of time than positive symptoms in the period immediately prior to hospitalization, particularly in children.

5.27.2.1.1 A case illustration

Jeremy is an eight-year old whose family moved to the US from England as he was approaching his sixth birthday. His father is a corporate executive and his mother works part-time as a literary agent. He resides with his parents and a 14-year old half-sister from his mother's previous marriage. The pregnancy and delivery were unremarkable and developmental milestones were reached within normal limits. His mother described Jeremy as a bright, active, and inquisitive toddler who needed to be monitored more closely than his sister at this stage to prevent accidents. Family history of psychiatric illness is largely negative with the exception of a paternal aunt who has a fear of heights. Jeremy's father believes that he may have been hyperactive as a child but he was never diagnosed or treated for the disorder; he attributed his behavior to being bored and unchallenged during grade school.

Jeremy started the first grade at a private school shortly after arriving in the US and began to exhibit noncompliant and aggressive behaviors. His teachers and parents initially attributed his behavioral problems to the family's recent move and the transition to a new school. Rather than subside over time, his negative behaviors began to escalate. A behavior management program was implemented by the school and it appeared to be modestly successful. By the end of second grade, however, Jeremy had become increasingly disruptive in the classroom, had begun to destroy other children's property, and was unable to sit still for any length of time. His school performance had declined substantially and he was performing in the low average range. Peer relations were similarly poor. He was referred for a psychiatric

Werry, McClellan, and Chard (1991)	30[c]	7–17	53	13	13		47		57

[a] Approximate estimate of age, derived from the mean and standard deviation provided in the report. [b] Not reported by subtype. [c] Three of the cases were below the age of 12.

evaluation, at which time he was diagnosed with attention-deficit hyperactivity disorder and started on a trial of methylphenidate. The stimulant trial resulted in a further deterioration of behavior whereby Jeremy's behavior became more agitated and unpredictable. This course of medication was discontinued, Jeremy was rediagnosed with chronic adjustment and conduct disorders, and he was referred for psychotherapy.

A psychiatric hospitalization was precipitated when Jeremy attempted to repeatedly stab a classmate with a sharpened pencil and, two days later, tried to choke his sister claiming that she was not his "real sister." Jeremy also had begun to pick at his skin and scabs until he drew blood, discussing the possibility of bleeding to death. On admission, Jeremy was neatly groomed and presented as a friendly but fidgety child with a short attention span. He reported hearing his name whispered but denied any other hallucinatory experiences. When questioned about the violent acts towards his classmate and sister, Jeremy stated that they were not who they seemed to be and that he had to kill the space aliens that had taken over their bodies in order for his real classmate and his real sister to come back to life. Jeremy refused to discuss his own self-injurious behavior and denied any suicidal ideation.

Upon admission to the hospital, physical and neurological exams proved to be normal. The patient made a good adjustment to the hospital environment and initially responded well to the behavior management program that was implemented. After a few days, however, Jeremy began to exhibit increasingly aggressive, chaotic, and disruptive behaviors. In addition, he resumed the practice of picking at his skin. The staff also observed occasional staring spells. An EEG was obtained and although a mild irregularity was observed, the follow-up magnetic resonance image was normal and did not support the possibility of a structural lesion. Jeremy slowly began to disclose psychotic symptoms that included auditory and visual hallucinations. For instance, Jeremy described a wizard appearing and although he could not always see him, the wizard would whisper his name and instruct him to hurt himself because he had disobeyed the rules. By making himself bleed, Jeremy reported that he could make the wizard go away. Jeremy also described seeing daggers that would drop down from the sky. At night, Jeremy was unable to sleep for the entire duration in his own room; he would awaken and attempt to bring a blanket to sleep on the floor next to the nursing station. Jeremy acknowledged that he was afraid but refused to reveal his specific fear, stating that disclosure would endanger other people. Over time, Jeremy became increasingly disorganized, his social relatedness declined considerably, and he would speak incoherently. He responded extremely well to a trial of risperidone, an atypical antipsychotic medication, that was offered along with supportive psychotherapy and exhibited no psychotic symptoms upon discharge. The total duration of hospitalization was 45 days.

5.27.2.2 Diagnostic Features and Differential Diagnosis

The *DSM-IV* and *ICD-10* definitions of schizophrenia are similar and, as noted, both use the same criteria for children, adolescents, and adults. The primary differences between the two systems is the degree to which diagnostic criteria are specified and the required duration for certain symptomatology, such that the *ICD-10* definition might be more liberal (Werry, 1996). This chapter focuses on *DSM-IV* criteria as this has been the predominant system used in recent studies on childhood-onset and adolescent schizophrenia. Extensive discussions of the similarities and differences between these two diagnostic systems, as well as comparisons with past systems, can be found in J. R. Asarnow (1994) and Werry (1996).

The *DSM-IV* criteria for schizophrenia (see Table 3) requires the presence of psychotic symptoms, accompanied by a deterioration in social and occupational functioning. In children and adolescents, this might be indicated by a failure to achieve the expected level in social development or academic achievement. Psychotic symptoms must be apparent for at least one month while signs of the disorder must persist for at least six months. Duration of symptoms is a particularly critical factor when considering a diagnosis of schizophrenia in children who might otherwise exhibit transient delusions or hallucinations (Rapoport & Ismond, 1996). Finally, symptoms cannot be attributed to another psychiatric disorder, medication, substance use, or a general medical condition. Subtypes of schizophrenia (i.e., paranoid, disorganized, catatonic, undifferentiated, and residual types) can be defined by the pattern of presenting symptoms but this typology appears to be less clearly differentiated in children than it is in adults (Rapoport & Ismond, 1996).

Because certain types of delusions and auditory hallucinations are seen as hallmarks of schizophrenia, they are weighted more heavily when making a diagnosis of schizophrenia. The presence of bizarre delusions or

Table 3 *DSM-IV* diagnostic criteria for schizophrenia.

A. *Characteristic symptoms*. Two (or more) of the following, each present for a significant portion of time during a one-month period (or less if successfully treated):
  (i) delusions
  (ii) hallucinations
  (iii) disorganized speech (e.g., frequent derailment or incoherence)
  (iv) grossly disorganized or catatonic behavior
  (v) negative symptoms, that is, affective flattening, alogia, or avolition
  Note: Only one criterion A symptom is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person's behavior or thoughts, or two or more voices conversing with each other

B. *Social/occupational dysfunction*. For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement)

C. *Duration*. Continuous signs of the disturbance persist for at least six months. This six-month period must include at least one month of symptoms (or less if successfully treated) that meet criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or two or more symptoms listed in criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences)

D. *Schizoaffective and Mood Disorder exclusion*. Schizoaffective Disorder and Mood Disorder with Psychotic Features have been ruled out because either (i) no Major Depressive, Manic, or Mixed Episodes have occurred concurrently with the active-phase symptoms; or (ii) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods

E. *Substance/general medical condition exclusion*. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition

F. *Relationship to a Pervasive Developmental Disorder*. If there is a history of Autistic Disorder or another Pervasive Developmental Disorder, the additional diagnosis of Schizophrenia is made only if prominent delusions or hallucinations are also present for at least a month (or less if successfully treated)

Required with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth edition. Copyright 1994 American Psychiatric Association.

auditory hallucinations involving commenting or conversing voices, therefore, is sufficient to satisfy criterion A, as shown in Table 3. As McKenna et al. (1994) indicate, thought processes may be developmentally immature in the younger patient but are not necessarily indicative of thought disorder or delusions. An adolescent, for instance, might engage in magical thinking which, while age-inappropriate, would not necessarily signify a psychotic disorder. Moreover, hallucinations are not uncommon in young children, and when they are accompanied by disorganized behavior they could lead to a misdiagnosis of schizophrenia. A key consideration, therefore, in making a diagnosis of schizophrenia in children and adolescents is the extent to which psychotic symptoms are pervasive and enduring rather than brief and transient. Disorganized speech is also likely to occur with increased frequency in children and may be indicative of a language deficit or communication disorder rather than schizophrenia (McKenna et al., 1994; Rapoport & Ismond, 1996). As noted by Volkmar and Schwab-Stone (1996), disorganized speech and grossly disorganized behavior in children may be nonpsychotic, and reliance upon these two characteristic symptoms will likely lead to a misdiagnosis of schizophrenia. Negative symptoms, such as affective flattening, can be difficult to distinguish from the psychomotor retardation that can accompany a mood disorder. Thus, the differential diagnosis of schizophrenia is not only critical but can prove to be a particular challenge in children and adolescents.

A misdiagnosis of childhood-onset schizophrenia, unfortunately, is not an uncommon event. McKenna et al. (1994) at the National Institute of Mental Health (NIMH) received more than 260 referrals from academic centers for children and adolescents with a presumptive diagnosis of childhood-onset schizophrenia. After screening the medical records, 71 children were evaluated at NIMH. Of this sample, fewer than 28% were found to meet diagnostic criteria for schizophrenia while the majority of children were best described by another diagnostic category. Misdiagnosis of schizophrenia is obviously a serious problem as the illness is associated with a relatively poor prognosis and neuroleptic medications that can have grave and potentially irreversible side effects. In addition to false-positives, false-negatives undoubtedly occur with some, as yet unknown, frequency.

One area that can prove to be confusing is the differential diagnosis of schizophrenia from other schizophrenia-spectrum disorders such as schizophreniform disorder, schizoaffective disorder, and schizotypal personality disorder. The primary distinction between schizophrenia and schizophreniform disorder is duration, with the latter requiring the presence of symptoms for less than six months. Schizophreniform disorder, however, is rarely diagnosed in childhood (Rapoport & Ismond, 1996). Schizoaffective disorder involves a concurrent manic or depressive episode during an uninterrupted and active phase of schizophrenic illness. As with adults, differentiating between schizoaffective disorder, mood disorder with psychotic features, and schizophrenia that is accompanied by brief disturbances in mood requires careful documentation of the time course and duration of symptoms. In general, the rate of psychotic symptoms accompanying depression is much higher than in adults, with estimates ranging from 48% in prepubertal depressed children (Chambers, Puig-Antich, Tabrizi, & Davies, 1982) to 31% in an inpatient sample of depressed adolescents (Strober, Lampert, Schmidt, & Morrell, 1993).

Schizotypal personality disorder also presents problems in the differential diagnosis of schizophrenia in children and adolescents. Because the onset of a schizophrenic disorder in children is generally insidious or subacute (J. R. Asarnow & Ben-Meir, 1988; McKenna et al., 1994), it may be difficult to distinguish schizotypal personality disorder from the premorbid phase of schizophrenia. In addition, premorbid schizoid traits have been found to occur with increased frequency among adolescents who subsequently develop schizophrenia (Dalkin, Murphy, Glazebrook, Medley, & Harrison, 1994).

Diagnostic confusion also can arise frequently between schizophrenia and mood disorders. McKenna et al. (1994) found that the majority of children in their sample were misdiagnosed with schizophrenia as a sizable group presented with major depression or bipolar disorder. Rapoport and Ismond (1996) caution that diagnoses such as mood disorder with psychotic features are often overlooked in children and that other depressive disorders also must be considered as well. Of course, many of the same issues must be considered in discriminating between a mood disorder and schizophrenia as when making a differential diagnosis with schizoaffective disorder. Discrimination between the irritability associated with depression and the inappropriate outbursts that can occur with schizophrenia, for instance, is one example of the type of difficulty that may be encountered when evaluating children and adolescents.

With certain anxiety disorders, there may be some similarities in symptom presentation. For instance, the recurrent ruminations and bizarre stereotyped behaviors that are associated with obsessive-compulsive disorder (OCD) could be mistaken for symptoms of schizophrenia. In adult patients, a key diagnostic feature of OCD is that obsessions and compulsions are seen as ego-dystonic or alien and not under the control of the patient. In children with a schizophrenic disorder, psychotic symptoms may seem relatively ego-syntonic and even "normal" given their longstanding presence in the child's life experience (Russell, 1994). Post-traumatic stress disorder also must be ruled out as flashbacks can be confused with the hallucinations that accompany schizophrenia.

The diagnosis of schizophrenia is made separately from the diagnosis of autistic and pervasive developmental disorders (see Table 3). This is specified explicitly in the *DSM-IV* criteria for schizophrenia, probably because of the previous practice of lumping autism and schizophrenia into a single diagnostic group labeled either "childhood schizophrenia" or "childhood psychosis." In fact, the diagnostic criteria for the two disorders are quite different. Autism involves qualitative impairments in both social interaction and communication as well as restricted and stereotyped patterns of behavior and interests. Moreover, delays or abnormal functioning have to occur before the child reaches three years of age, whereas schizophrenia is rarely manifested or detected before six to seven years. Finally, children diagnosed with schizophrenia also tend to have low to normal intellectual functioning, whereas 70–80% of children with autism are also mentally retarded. Diagnostic confusions sometime arise in older, nonretarded children with autism. In some of these children, their preoccupations with stereotyped areas of interest can seem somewhat delusional and some children with autism have communication deficits that include loose associations and illogical thinking. A small number of autistic children develop true hallucinations and delusions (Petty, Ornitz, Michelman, & Zimmerman, 1984) but this tends to be rather infrequent (Volkmar & Cohen, 1991). Asperger's syndrome is a rare form of autism in which the children do not exhibit any communication disorder but do show problems in social interactions and preoccupations with stereotyped interests; these children do not manifest the psychotic symptoms associated with children diagnosed with schizophrenia.

The alternative diagnoses considered thus far are not intended to represent an exhaustive list of candidates. Certainly, numerous other possibilities (e.g., delusional disorder, substance-induced psychotic disorder, psychotic disorder due to a medical condition, degenerative neurological disorders) must be considered along with a diagnosis of schizophrenia (see Rapoport & Ismond, 1996). Even granting that tremendous caution is taken before conferring a diagnosis of schizophrenia on a child, adolescent, or adult, misdiagnoses still can occur with considerable frequency.

Several processes may contribute to diagnostic misclassification of schizophrenia in children and adolescents. One possibility, mentioned earlier, is that it can be difficult to establish the presence of some symptoms, particularly in younger children; symptoms may be overlooked, misinterpreted, or remain uncorroborated. As McKenna et al. (1994) found, schizophrenia also may be applied overinclusively to severely disturbed children who exhibit psychotic symptoms. In their sample, almost one-third of the children did not meet diagnostic criteria for schizophrenia but were best-described as "multidimensionally impaired" (MDI). Such a group of children highlight the continued need to improve upon our current diagnostic classification schemes (Volkmar & Schwab-Stone, 1996). Another factor that may lead to a failure to diagnose schizophrenia is that the characteristic symptoms of the illness may only emerge over time. Children later found to have a schizophrenic disorder, for example, may initially present with significant behavioral problems and receive an attention-deficit or disruptive behavior disorder diagnosis (e.g., Russell, 1994). Still another subset of children may initially present with a disorder, such as psychotic mood disorder (Werry et al., 1994), and only later develop schizophrenia. Finally, as illustrated by Werry et al. (1991), a diagnosis of schizophrenia may precede the onset of a psychiatric disorder such as bipolar disorder.

The diagnostic process is further complicated by the high rate of co-occurrence of other psychiatric disorders with childhood-onset schizophrenia. Russell et al. (1989) determined that 69% of their sample of children with schizophrenia met diagnostic criteria for another psychiatric disorder. Associated diagnoses occurring with the greatest frequency were conduct disorder (29%), atypical depression (26%), dysthymia (11%), and enuresis or encopresis (14%). Among adolescent patients, schizophrenia may coexist with a substance abuse disorder. Werry et al. (1994), for instance, reported a 54% comorbidity rate in their US sample. Although a small number of autistic children have been found to later develop schizophrenia (Petty et al., 1984), there does not appear to be a comorbid association between autism and schizophrenia (Volkmar & Cohen, 1991).

5.27.2.3 Prevalence

The potentially high rate of misdiagnosis of schizophrenia in children and adults is due in part to its rarity. Estimates of the incidence of schizophrenia in childhood range from 0.19 to 1 in 10 000 (Beitchman, 1985; Burd & Kerbeshian, 1987; Gillberg, Wahlstrom, Forsman, Hellgren, & Gillberg, 1986; Häfner & Nowotny, 1995). In adolescence, schizophrenia continues to be rare although it shows a steady increase with each successive year (Gillberg et al., 1986; Häfner & Nowotny, 1995). With the majority of cases of schizophrenia developing during late adolescence and early adulthood, schizophrenia occurs in about 1% of the population across the entire lifespan.

Among childhood-onset schizophrenia cases, there is a consistent sex difference with males exceeding females by a ratio of about 2:1 (Green et al., 1992; Hollis, 1995; Kolvin et al., 1971; Russell et al., 1989; Volkmar et al. 1988). These differences, however, disappear by adolescence where the distribution appears to be equal for both sexes (Hollis, 1995; Remschmidt et al., 1991; Schmidt, Blanz, Dippe, Koppe, & Lay, 1995; Werry et al., 1991). Various suggestions have been offered to explain the apparent influence of age on the sex distribution of schizophrenia in young patients, including the possibility of etiological differences with males showing greater biological vulnerability (J. R. Asarnow, 1994).

5.27.2.4 Etiology

Research examining the relationship between schizophrenia in children and adults has indicated a strong likelihood that the two forms of the disorder are continuous. In addition to the investigations into the phenomenology of childhood-onset schizophrenia described earlier, studies on brain morphology (Frazier et al., 1996), event-related potentials (Strandburg, Marsh, Brown, R. F. Asarnow, & Guthrie, 1994), autonomic responsivity (Zahn et al., 1997), smooth pursuit eye tracking (Gordon, Frazier et al., 1994), attention and information processing (R. F. Asarnow, Brown, & Strandburg, 1995), and reaction time (Zahn et al., in press) in children have found similar patterns of abnormalities to those observed in adults with schizophrenia. Evidence also exists to suggest that childhood-onset schizophrenia may represent a more homogenous and severe form of the disorder as the genetic loading for schizophrenia, degree of central nervous system dysfunction, and level of environmental insult or stress may be higher in children than in adults with schizophrenia (J. R. Asarnow, 1994; McKenna, Gordon, & Rapoport, 1994).

Additional efforts to understand the etiology of childhood- and adolescent-onset schizophrenias, thus far, are represented largely by the application and extension of theories developed to explain schizophrenia in adults. This research has consistently failed to support the notion that there is a single cause of schizophrenia, and instead, accumulating evidence suggests that schizophrenia is a heterogenous disorder with multiple causes and presentations. Several of the prevailing theories of schizophrenia will be considered.

Considerable evidence indicates genetic contributions to schizophrenia. Results of family and twin studies suggest concordance rates of about 6% in a parent, 9% in a sibling, 13% when one parent is affected, 17% in dizygotic twins, 46% when both parents are affected, and 48% in monozygotic twins (Gottesman, 1991). These findings have been bolstered by the results of adoption studies that demonstrate the genetic influence on schizophrenia although familial environment also appears to play a role (e.g., Kety, Rosenthal, Wender, & Schulsinger, 1976; Tienari et al., 1987). Preliminary findings from the NIMH study on childhood-onset schizophrenia suggests that 13.6% of the children have first-degree relatives with non-affective psychotic disorders. It is likely, however, that this is an underestimate of a possible genetic influence due to a small sample size and selection bias (Gordon, Frazier et al., 1994). In one child diagnosed with a schizophrenic disorder, there was an apparently balanced translocation involving chromosomes 1 and 7 which, when combined with evidence from other research, suggests a potential gene locus for developmental brain disorders (Gordon, Krasnewich, White, Lenane, & Rapoport, 1994).

Although the evidence for a genetic contribution to schizophrenia is strong, genetic heritability cannot account for all cases of schizophrenia nor does it explain instances whereby the monozygotic twin of a schizophrenic patient fails to develop the illness. Several lines of evidence suggest that other personal and environmental factors may lead to schizophrenia or may influence the outcome of an underlying genetic predisposition. Weinberger (1987) has proposed that schizophrenia is a neurodevelopmental disorder in which a fixed brain lesion or some pathologic condition of the brain occurs early in life. This lesion or brain pathology is likely to involve the dopaminergic neural systems and the prefrontal cortex. Over the normal course of maturation of the neural system, the brain lesion becomes evident with the onset of schizophrenic symptoms. Weinberger suggests that schizophrenia may be rare in children but more common in older adolescents and young adults as maximum dopaminergic activity in the brain does not occur until early adulthood. As for the cause of the lesion, numerous possibilities exist. Mednick, Machon, Huttunen, and Bonett (1988), for instance, have found that maternal exposure to a severe influenza during the second trimester is associated with an elevated frequency of adult schizophrenia in the offspring.

Psychosocial factors also may have a significant impact on the course of schizophrenia. Communication deviance (CD), which refers to an unclear, confusing, and fragmented communication style (Singer & Wynne, 1963), has been found to occur more frequently in the parents of adult schizophrenic patients (e.g., Singer & Wynne, 1965), adolescents at risk of schizophrenia and related disorders (Goldstein, 1987), and children diagnosed with schizophrenia or schizotypal personality disorder (J. R. Asarnow, Goldstein, & Ben-Meir, 1988). The etiological relationship, if any, between CD and schizophrenia is unclear, although it has been suggested that CD may represent an environmental stressor or a biological predisposition to schizophrenia in parents that is reflected in subtle levels of disordered thought or communication (Singer & Wynne, 1965; Miklowitz et al., 1991).

Another psychosocial factor that may contribute to the course of schizophrenia is expressed emotion (EE) or the degree to which critical and emotionally overinvolved attitudes are conveyed to the schizophrenic patient. As reviewed by Goldstein, Strachan, and Wynne (1997), numerous studies have shown that high levels of EE predict relapse among schizophrenic adults. In contrast, the association between EE and schizophrenia in children appears to be less robust although parents of children with schizophrenia or a related condition have been found to be more likely to express harsh criticisms toward their child compared with parents of normal children (J. R. Asarnow et al., 1994; Hamilton, 1991). On the basis of these data, it is not clear if harsh criticisms arise in response to dealing with a child with a severe mental illness, if some family members of schizophrenic patients tend to express critical comments that contribute to symptoms, or perhaps most likely, if the emotional environment of the family reflects a combination of these factors.

5.27.2.5 Developmental Course

The developmental course of schizophrenia in children and adolescents entails consideration of a broad range of issues, beginning with premorbid adjustment and extending to the prodromal phase, the course of the schizophrenic episode, and subsequent outcome of the disorder that may include relapse. Premorbid adjustment, or the child's level of functioning prior to the onset of schizophrenia, has been found to range from normal to uneven development (Gordon, Frazier et al., 1994). In reviewing the premorbid history of children diagnosed with schizophrenia, several studies have found delays on one or more developmental milestones in approximately one-half of children examined, with the largest and most frequent lags typically occurring in the areas of language and gross motor development (Alaghband-Rad et al., 1995; Hollis, 1995; Watkins, R. F. Asarnow, & Tanguay, 1988). It is clear that a number of childhood-onset schizophrenic patients also experience difficulty with academic performance and school adaptation (J. R. Asarnow et al., 1994; Hollis, 1995). Alaghband-Rad et al. (1995) observed that over half of their sample repeated at least one grade; a substantial proportion had received placements in special education classes and estimates of premorbid IQ tended to be in the low to normal range.

In terms of social development, approximately one-half of patients diagnosed with childhood-onset schizophrenia have been noted to exhibit significant impulsivity and approximately half were viewed as relatively withdrawn and socially impaired (Alaghband-Rad et al., 1995; Hollis, 1995). It is not surprising that when assessed, peer relationships also were quite poor with childhood-onset schizophrenic patients showing significantly greater levels of impairment than children diagnosed with major depressive disorder (J. R. Asarnow et al., 1994).

For some children, the presence of significant developmental delays or disruptive behaviors has been associated with other psychiatric disorders. Approximately one-third of schizophrenic children have a premorbid history marked by at least some feature of pervasive developmental disorder while about one-third have a premorbid history of attentional and hyperactivity problems (Alaghband-Rad et al., 1995; Russell et al., 1994). Overall, Russell (1994) concluded that 86% of their sample had a history of some behavioral or psychiatric disturbance prior to the emergence of psychotic symptoms. There is some evidence to suggest that childhood-onset patients with schizoaffective disorder may tend to have a better premorbid course than children diagnosed with schizophrenia (Eggers, 1989).

The premorbid course for adolescent-onset schizophrenia also appears to be generally poor. In samples obtained in New Zealand and the United States, Werry et al. (1994) observed that 83% of participants exhibited odd, anxious, or disruptive personality styles and that the typical patient had a history of poor adaptive functioning. In comparing the premorbid course between childhood- and adolescent-onset cases, Hollis (1995) found that children with schizophrenia were more likely to have a history of impaired language or speech development. The onset of schizophrenia in early adolescence was more likely to be accompanied by a history of restless and fidgety behavior although there was no significant difference between the two groups in motor development.

The onset of schizophrenia in children is typically gradual and insidious, with an extensive prodromal phase of behavioral disturbance that eventually leads to the emergence of psychotic symptoms. The prodromal period might be characterized by attentional problems, hyperactivity, declines in school performance, poor peer relationships, deterioration in daily functioning (e.g., performing personal hygiene), and social withdrawal (e.g., Green et al., 1992; McKenna et al., 1994; Russell et al., 1989; Watkins et al., 1988). An acute onset of psychotic symptoms appears to be be more characteristic of schizophrenia in adolescents and some adults (e.g., Hollis, 1995; Werry, 1996).

While research into the course of schizophrenia as it occurs in children and early adolescents is quite limited, the available data suggests that many patients will experience recurrent episodes of schizophrenia. J. R. Asarnow et al. (1994) contacted childhood-onset patients one year after discharge from the hospital and found that 89% of their sample continued to meet diagnostic criteria for schizophrenia or schizoaffective disorder rather than some other psychiatric disorder. When the same patients were followed up after 2–7 years, 61% of the sample was diagnosed with schizophrenia while 33% was in remission. Among remitted patients, only one child was free of symptoms two years after their initial hospitalization. Similar rates have been obtained by Eggers (1989) who observed complete remission in 27% of schizophrenic patients included in his study. In comparing children diagnosed with schizophrenia to those with schizoaffective disorder, the rate of remission appears to be comparable although the overall prognosis appears to be better for schizoaffective patients. In both cases, there is evidence to suggest an unremarkable premorbid history is associated with a more favorable outcome (Eggers, 1989).

Among patients diagnosed with adolescent-onset schizophrenia, Werry et al. (1994) similarly found that over 80% continued to experience psychotic episodes two years after follow-up. Schmidt et al. (1995) contacted adolescent-onset patients 1–15 years after the index hospitalization and found that 27% had no further schizophrenic episodes. As with childhood-onset cases, normal premorbid adjustment has been found to be predictive of a good outcome (Werry et al., 1994).

5.27.3 CONCEPTUALIZATION AND CLINICAL FORMULATION

5.27.3.1 Multimodal Assessment

Formulating a diagnosis of schizophrenia in a child or adolescent is obviously a serious proposition given the social stigma, relatively poor prognosis, and potentially irreversible side effects that can accompany antipsychotic medications. As noted earlier, a number of factors may contribute to the misdiagnosis and overdiagnosis of schizophrenia in children and adolescents. Notwithstanding these considerations, care also must be taken to avoid underutilization of this diagnostic category; failure to make a diagnosis of schizophrenia could perpetuate suffering and preclude patients from receiving necessary treatment and appropriate services (McClellan & Werry, 1994). Given the multitude of issues that need to be confronted in considering a diagnosis of schizophrenia in a child or adolescent, a thorough and multimodal assessment is clearly indicated.

Perhaps the first step involved in the diagnostic assessment of schizophrenia in children and adolescents is to obtain a thorough and detailed premorbid history as well as a comprehensive evaluation of the prodromal period and current level of functioning. Development, intellectual functioning, academic achievement, cultural considerations, and family psychiatric history and background are all crucial factors that need to enter into any consideration of possible psychotic symptoms. A challenge inherent to any assessment of schizophrenia in children and adolescents is distinguishing true psychotic manifestations from idiosyncratic thinking and perceptions associated with developmental delays, speech and language disturbances, vivid imaginations, exposure to an extreme traumatic stressor, as well as religious ideation (e.g., McClellan & Werry, 1994; McKenna et al., 1994). A thorough pediatric and neurological evaluation is also indicated to rule out the possibility of an organic psychosis. Results of an investigation by Adams, Kutcher, Antoniw, and Bird (1996) in adolescent-onset schizophrenic patients suggest that current, routine endocrine, and neuroimaging screening tests are of no diagnostic utility unless symptoms suggestive of neurological or endocrinological disorders are present.

Reliance on multiple informants that include the child or adolescent, parents, teachers, caretakers, and other significant individuals is likely to yield the most information and improve diagnostic accuracy. As described above, psychotic symptoms may be initially associated with other psychiatric disorders or they may not be obvious, particularly in younger children. A child, for instance, may initially present with significant behavioral disturbance and receive a diagnosis of conduct disorder or attention-deficit hyperactivity disorder. Months may elapse before the clinical presentation of psychotic symptoms becomes apparent and even then, the disturbances may not present across situations or be evident to all potential informants. Alternatively, some children and adolescents with schizophrenia will require hospitalization because of suicidal, aggressive, or dangerous behavior problems. As illustrated in the case study described earlier, a psychiatric hospitalization may be beneficial when considering a diagnosis of schizophrenia in younger patients as it can provide an excellent opportunity to observe and document a range of behaviors in a controlled setting.

Regardless of whether the evaluation is conducted on an inpatient or outpatient basis, it is critical that the range of symptoms be thoroughly assessed. Reliable and well-validated structured diagnostic interview schedules, such as the Schedule for Affective Disorders and Schizophrenia for School-Age Children-Epidemiologic Version (K-SADS-E; Orvaschel, 1995) and the Diagnostic Interview for Children and Adolescents (DICA; Herjanic & Reich, 1982), are currently available to guide clinicians and clinical researchers through a detailed examination of various diagnoses in children and adolescents. Werry (1996) cautions that structured interviews may be tedious but are clearly warranted given the seriousness of the diagnoses under consideration. Systematic coverage of symptoms is particularly useful when attempting to resolve some of the complexities in distinguishing between disorders. (See McKenna et al. (1994) and McClellan and Werry (1994) for excellent discussions of other key diagnostic issues.)

In addition to diagnostic interviews, a number of rating scales exist for assessing specific schizophrenic symptoms such as thought disorder, negative symptoms, and positive symptoms. These measures include the Kiddie Formal Thought Disorder Rating Scale (K-FTDS) and Story Game (Caplan, Guthrie, Fish, Tanguay, & David-Lando, 1989), Thought Disorder Index (TDI; Arboleda & Holzman, 1985), Scale for the Assessment of Negative Symptoms in Schizophrenia (SANS; Andreasen, 1983), and Scale for the Assessment of Positive Symptoms in Schizophrenia (SAPS; Andreasen, 1984). Although some of these measures have traditionally been used in clinical research settings, they may be appropriate for clinical practice as well. It is important to note that while psychotic symptoms are the hallmark of schizophrenia, most children who report hallucinations are not schizophrenic as they do not present with all of the requisite diagnostic symptoms (McClellan & Werry, 1994). The use of reliable and valid measures of thought disorder that have been found to discriminate between children with schizophrenia, other psychiatric disorders, or no history of psychiatric illness, therefore, can be helpful in ascertaining perceptual, language, and communication disturbances. Moreover, the importance of developmental effects on the K-FTDS and TDI have been demonstrated (Arboleda & Holzman, 1985; Caplan et al., 1989; Caplan, Perdue, Tanguay, & Fish, 1990), so both measures can potentially serve as useful guides in differentiating between age-appropriate and abnormal behaviors.

Finally, children or adolescents who have received an initial diagnosis of schizophrenia will need to be closely monitored and reassessed periodically to determine the course of illness, the impact of treatment, and level of functioning. As demonstrated by McKenna et al. (1994) and Werry et al. (1991), a significant proportion of children and adolescents who are initially diagnosed with schizophrenia are later found to exhibit a different psychotic disturbance, such as bipolar disorder or schizoaffective disorder. Diagnostic reassessment, in some instances, may be complicated by the effects of pharmacological treatments which can lead to a partial, or even, complete remission in symptoms. Over time and with treatment, symptom patterns also are likely to change and influence the patient's level of functioning accordingly. In some instances, it may be difficult to distinguish between maturational effects and change due to clinical improvement. There also may be marked discrepancies in degree of improvement across domains, such that premorbid levels of functioning may be reached in some areas but not in others. J. R. Asarnow et al. (1994) have demonstrated that there is considerable variability in the course of schizophrenic illness with some children exhibiting deterioration while others show minimal or even substantial improvement over time. Psychoeducational assessment of multiple domains of functioning at multiple points in time, therefore, provides opportunities to determine current strengths and weaknesses for a child and any modifications that might be needed in service provision.

5.27.3.2 Treatment Formulation

A diagnosis of schizophrenia is naturally a devastating event for a child or adolescent and their family members. As with any psychiatric illness, the initial diagnosis may be met with denial or even relief as an explanation has been found for unusual and perhaps frightening behavior. Treatment, therefore, ideally should be oriented not only towards the child but towards addressing the needs of their families as well.

Neuroleptic medication is generally regarded as the cornerstone of treatment for schizophrenia in children, adolescents, and adults. While pharmacological treatment may be considered necessary, it is not sufficient. Various clinical researchers (e.g., Kane, 1987) have recommended that schizophrenia in adults be approached in phases, each with different strategies and goals. The first phase involves the acute presentation of florid psychotic symptoms, and therefore, the necessary emphasis is on the use of antipsychotic drugs to decrease the severity of symptoms. Oftentimes, the child or adolescent will have been admitted to the hospital at this point. Once the acute phase is controlled, there is a stabilization period in which some psychotic symptoms will have improved while others may continue to persist. The third phase is reached once most psychotic symptoms have resolved. During these latter two periods, psychosocial and school-based interventions become critical factors in improving the quality of life, decreasing the likelihood of relapse, and meeting educational needs. When appropriate, rehabilitation programs may help to optimize the social and occupational outcome for many children and adolescents with schizophrenia. Depending upon symptom course and the effectiveness of pharmacologic interventions, residential or day treatment programs may need to be considered.

As with any child who has a debilitating and potentially chronic condition, case management services may be essential to obtaining necessary social services. Access to services can have far-reaching effects. Compliance with neuroleptics, for example, may depend upon the availability of funds for purchasing medication. In general, the burden experienced by family members, who are required to care for a child or adolescent with schizophrenia, can be alleviated to some extent if caregivers can receive guidance on how to access relevant resources. Family psychoeducational programs, which are discussed below, and family advocacy groups may be of substantial benefit to family members of children and adolescents diagnosed with schizophrenia as well as to the patients themselves.

The American Academy of Child and Adolescent Psychiatry (AACAP) has developed a detailed set of practice parameters for the diagnosis and treatment of children and adolescents with schizophrenia (McClellan & Werry, 1994). Although these practice parameters were developed to assist physicians, other clinicians may find the guidelines useful. A number of diagnostic and treatment recommendations are offered that reflect recent research knowledge and advancements in childhood and adolescent-onset schizophrenia.

5.27.4 TREATMENT

5.27.4.1 Psychosocial Treatments

The schizophrenic child or adolescent is likely to face interpersonal, behavioral, and intellectual challenges. Intervention programs, therefore, need to be designed to not only treat the schizophrenic illness but also meet the unique needs of each child.

In light of the earlier discussion on premorbid course, it would be reasonable to expect that many children and adolescents diagnosed with schizophrenia will have exhibited delays in certain areas of functioning, such as language, gross motor, or social development. With the onset of the illness, normal developmental progress may be impeded further. Individualized school programs may need to be developed, therefore, to accommodate the educational needs of a child diagnosed with schizophrenia. Reintegration into the classroom or school may require academic remediation as well as assistance with modifying inappropriate social behaviors and developing suitable social skills. In the classroom, for instance, behavioral interventions may be necessary for minimizing disruptive behaviors and increasing appropriate behaviors.

Social skills training may be helpful in eliminating or reducing the boundary that may exist between a child or adolescent with schizophrenia and his or her peers. With adult patients diagnosed with schizophrenia, skills-focused training leads to more effective interpersonal functioning and improved social adjustment, particularly among patients with a relatively early onset of illness (Marder et al., 1996). The authors speculate that adults with an earlier onset of schizophrenia may have been more socially deficient as they had less time to develop interpersonal skills prior to the onset of their illness, and therefore, may have benefited more from the training program. Such a scenario would argue in favor of implementing social skills training with children and adolescents. To the best of our knowledge, a comprehensive social skills training program has yet to be adapted for children and adolescents with a severe psychiatric disturbance, although an effective program has been developed for adult patients with schizophrenia (Liberman, DeRisi, & Mueser, 1989).

Individual psychotherapy is a traditional mode of treatment for children and adolescents with any psychiatric disturbance. Such approaches typically range from supportive therapies and behavioral or cognitive-behavioral strategies to insight-oriented therapies. AACAP (McClellan & Werry, 1994), however, cautions against the use of insight-oriented therapies, particularly during the acute phases of illness. More recently, psychoeducational family intervention programs have generated considerable interest.

As discussed earlier, there may be an association between the emotional environment of the family and a propensity towards relapse. Current psychoeducational family treatment programs, in contrast to previous techniques, focus on the present and encourage the patient to gradually re-enter the family environment. Family treatment recognizes that intrafamilial processes arise from the complex transactions between family members and patients, who can pose genuine difficulties for their relatives and the resources available to those relatives. Rather than attempt to establish a causal link between families and the patient's illness, treatment is oriented towards assisting patients and their families in the effective management of the illness (Goldstein & Miklowitz, 1995). Although there are various forms of psychoeducationally-oriented family treatment programs, they share certain features that likely contribute to their effectiveness. These include engaging family members early in treatment;

encouraging an open atmosphere rather than attempting to assign fault; educating families about the phenomenology, course, prognosis, etiologic models, and rationale behind different treatments; offering recommendations for coping with the disorder; providing training on improving communication and problem-solving skills; and performing crisis intervention (Goldstein & Miklowitz, 1995). Family intervention can be based in the home or clinic, may involve individual or multiple families, and may include or exclude the patient. As with social skills training, systematic application of psychoeducational family intervention programs appears thus far to have been limited to adult populations.

For some children or adolescents with schizophrenia, a residential treatment center or other out-of-home placement may need to be considered. In a follow-up study of child psychiatric inpatients, J. R. Asarnow, Goldstein, Carlson et al. (1988) found that 57% of children with a schizophrenia spectrum disorder were placed out of the home within 13 months of being discharged from the hospital; the majority were placed in residential treatment centers. The decision to place a child or adolescent out of the home is obviously a complicated issue, around which multiple determining factors may operate. The extent to which long-term therapeutic placements are utilized is likely to depend, in part, on how a patient responds to pharmacological treatment and medication compliance, a topic to which we now turn.

5.27.4.2 Pharmacological Treatments

Children and adolescents diagnosed with schizophrenia have largely received the same medication treatments as adult patients. Pharmacological agents have included conventional neuroleptics such as haloperidol (Haldol), loxapine (Loxitane), thiothixene (Navane), thioridazine (Mellaril), and pimozide (Orap) (Spencer & Campbell, 1994). Treatment with these antipsychotic medications has often been limited by accompanying side effects, such as sedation, weight gain, and extrapyramidal symptoms (EPS) which include dystonia, akinesia, akathisia, and tremor. With conventional neuroleptic treatment of schizophrenia in children and adolescents, there also is the possibility of withdrawal dyskinesia and a potentially irreversible movement disorder, tardive dyskinesia (McClellan & Werry, 1994). More recently, atypical neuroleptic medications such as clozapine (Clozaril) and risperidone (Risperdal) have been introduced. Both of these newer atypical antipsychotic agents appear to be associated with less EPS (Findling, Grcevich, Lopez, & Schulz, 1996; Kumra et al., 1996). Clozapine, however, has been reserved for treatment-refractory patients as patients treated with this medication must be closely monitored for agranulocytosis and seizures (Kumra et al., 1996).

5.27.4.3 Efficacy of Treatments

As mentioned earlier, it does not appear that a formal social skills training program exists for children and adolescents. In Germany, Remschmidt et al. (1994) have developed a rehabilitation program that was deemed necessary for about 40% of the schizophrenic children and adolescents at their hospital. Results of their study suggest that it was possible to gradually reintegrate most patients back into their families, schools, or professional training programs.

Despite their longstanding tradition, the effectiveness of individual psychotherapies with children and adolescents with schizophrenia has yet to be determined. In schizophrenic adults, results of several controlled trials failed to indicate that individual psychotherapy, either alone or combined with pharmacotherapy, contributed significantly to remission after a psychotic episode or prevention of relapse once the patient had returned to the community (Goldstein, 1989). Psychoeducational family education programs, in contrast, when combined with medication management, have consistently been shown to reduce the likelihood of relapse beyond that associated with medication alone in adult patients. Moreover, there is evidence to suggest that when combined with pharmacologic treatment, family interventions are more effective over a two-year period than individual therapies in delaying relapses and improving social functioning (Goldstein & Miklowitz, 1995). Although there is little reason to doubt that similar effects would not be observed in children and adolescents with schizophrenia, it remains an empirical question as to whether younger patients would obtain similar benefits from family education.

There have been few studies on the effectiveness of neuroleptic medication with children and adolescents; the efficacy of such treatments has been based primarily on extrapolations from double-blind comparison studies conducted with adult schizophrenic patients and case studies involving children and adolescents. In one of the earliest studies utilizing a double-blind and placebo-controlled design, Pool, Bloom, Wielke, Roninger, and Gallant (1976) demonstrated that loxapine and haloperidol were superior to placebo in treating a large sample of adolescents diagnosed with schizophrenia. Spencer and Campbell (1994) similarly found haloperidol to have superior effects over placebo in children with schizophrenia. In a double-blind study comparing an atypical agent with a typical neuroleptic, clozapine was shown to be a more effective form of treatment than haloperidol on all administered measures of psychosis (Kumra et al., 1996). These data are particularly striking as only children who were found to be nonresponsive to at least two typical neuroleptics were included in the study. Results of a case study (Quintana & Keshavan, 1995) and a retrospective chart review study (Findling et al., 1996) suggest that another atypical antipsychotic medication, risperidone, also may be efficacious in the treatment of children and adolescents with schizophrenia.

5.27.5 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

With the shift in the late 1970s and 1980s towards greater diagnostic specificity of schizophrenia in childhood and adolescence, a nucleus of clinical research findings began to emerge, supporting the possibility of early-onset forms of schizophrenia. As reviewed in this chapter, a number of similarities were found to exist between child, adolescent, and adult forms of schizophrenia when the same diagnostic criteria were applied. Seeking to determine the degree of continuity with adult schizophrenia was a critical and natural first step. As the fields of childhood- and adolescent-onset schizophrenia mature, however, it will be important to not only continue to extrapolate from the adult research literature and seek similarities and differences between the various forms of schizophrenia but to move towards elucidating a developmental perspective on schizophrenia in children and adolescents. There has been notable movement in this direction, such as the work by Caplan (e.g., Caplan, 1994) on the influence of maturation on communication skills and the assessment of thought disorder.

Because of the many developmental issues that can arise, further progress is needed to assist with diagnostic ambiguities. Overdiagnosis of schizophrenia in children and adolescents is occurring at an alarming rate (McKenna, Gordon, Lenane et al., 1994). Misdiagnoses, such as with attention-deficit hyperactivity disorder, also are not uncommon. As more standardized measures of various aspects of schizophrenia become implemented, diagnostic decisions can become more reliable and valid. Identification of more homogenous samples will also greatly facilitate comparisons of studies conducted by different research groups. In addition, attention needs to be directed to understanding children with psychopathological conditions that appear to fall on the borderline of schizophrenia, such as the MDI group that was identified by McKenna et al. (1994).

The relative youth of the area is underscored by the meager number of longitudinal and long-term follow-up studies. Information from such investigations is crucial to our understanding of schizophrenia in children and adolescents and to its treatment. For instance, it will be important to determine the extent to which course of illness is influenced by stressors in the child's environment as well as protective factors. Information on the long-term course of schizophrenia as child and adolescent patients enter into adulthood will be of considerable utility as patients and their families prepare for the future.

For clinical researchers, childhood-onset schizophrenia provides a unique opportunity to trace the etiologic underpinnings of a rare, but presumably more homogenous form of schizophrenia. The available evidence suggests that childhood- and adolescent-onset schizophrenia are distinct forms of the illness. Accordingly, continued comparisons between these groups will help shed light on the underlying neuropathology as well as the influence of age of onset on neurocognitive and behavioral disturbances in schizophrenia.

Perhaps the most striking deficiency in the literature at present is the relative paucity of research on the efficacy of psychosocial treatments of schizophrenia when diagnosed in children and adolescents. Drawing from the literature on adult schizophrenic patients, it would appear that the development of social skills training programs for children and adolescents, and psychoeducational family intervention programs for their families, are clearly warranted. With such programs in place, multimodal treatment studies could then be conducted to determine the most effective form of treatment for these young patients. As Campbell and colleagues (Campbell & Cueva, 1995; Spencer & Campbell, 1994) have noted, additional research is also needed to assess the use of atypical neuroleptics with younger children and the long-term effects of all antipsychotic medications in children and adolescents with schizophrenia.

Considerable progress has been made in understanding childhood- and adolescent-onset schizophrenias. This is particularly noteworthy in light of the fact that this is a rare and often difficult to diagnose disorder. Further research will assist not only with improving our understanding of schizophrenia but with alleviating the distress and disruptions experienced by children and adolescents diagnosed with schizophrenia and their families.

5.27.6 SUMMARY

Schizophrenia is uncommon in childhood and adolescence, with prevalence estimates ranging from 0.19 to 1 in 10 000. By a ratio of about 2:1, male children are more likely than female children to be diagnosed with schizophrenia. Male and female adolescents, in contrast, are about equally likely to receive this diagnosis. Diagnosis of childhood- and adolescent-onset forms of schizophrenia involves the same criteria as adult forms of the disorder, although developmental variations can complicate diagnostic decision-making. Distinguishing psychotic thought disturbances from idiosyncratic thinking associated with developmental delays, language disturbances, vivid imagination, and stress responses may be difficult but, nonetheless, is essential.

Auditory hallucinations have been noted in approximately 80% of children diagnosed with schizophrenia, along with high rates of visual hallucinations, delusions, formal thought disorder, and inappropriate or flat affect. The presence of pervasive and enduring psychotic symptoms is necessary for making a diagnosis of schizophrenia, and careful documentation of the time course and duration of symptoms is essential for accurate classification. A high rate of misdiagnosis may be quite common (McKenna et al., 1994), with a complex presentation of symptoms and the presence of comorbid conditions often complicating the diagnostic picture. In particular, schizophrenia in children and adolescents is often confused with other schizophrenia-spectrum disorders, major depression, bipolar disorder, and mood disorder with psychotic features. Given the complexity of this disorder and its diagnosis, the use of multiple informants and structured interviews is strongly recommended. Moreover, because change in symptom patterns is common, frequent reassessment is necessary.

With regard to etiology, there appears to be marked continuity between childhood-onset schizophrenia and adult forms of the disorder. Research suggests that childhood-onset schizophrenia is a more homogeneous and severe form of the disorder, in terms of genetic loading, central nervous system dysfunction, and level of environmental insult or stress. As with adult forms of the disorder, theoretical models relating to children and adolescents emphasize the interplay of genetic and environmental factors. However, the adult models may need to be altered to account for biological changes that occur with time. For instance, key aspects of dopaminergic functioning may be low in childhood and increase into early adulthood or, to account for the increased salience of environmental variables, the quality of family communication may prove to be more etiologically significant at different points along the lifespan.

The onset of schizophrenia in children is typically gradual, with an extensive prodromal phase that is marked by attentional problems, hyperactivity, and deterioration in school and social functioning. Acute onset appears to be more common among adolescents and adults. Most children who are eventually diagnosed with schizophrenia have some history of developmental delays, behavioral difficulties, and social impairment; the premorbid course for individuals diagnosed with adolescent-onset schizophrenia is also poor. Recurrence of symptoms is common among childhood- and adolescent-onset cases, although an unremarkable premorbid history may be related to a more favorable outcome.

Treatment of schizophrenia in children and adolescents should be multimodal with pharmacological interventions forming the cornerstone. Conventional neuroleptics as well as atypical antipsychotic agents have been found to be successful in treating children and adolescents with schizophrenia. In adult patients with schizophrenia, their effectiveness in delaying relapses and improving social functioning is significantly improved when combined with a psychoeducational family intervention program. Comparable effects with childhood- and adolescent-onset cases are likely but have not yet been documented. School-based and social skills training interventions may also be beneficial.

In sum, considerable progress has been made in understanding and treating children and adolescents who are diagnosed with schizophrenia. Continued research, particularly involving prospective longitudinal designs, is needed to obtain a better understanding of the presentation, diagnosis, causes, course, and treatment of schizophrenia in children and adolescents.

ACKNOWLEDGMENT

This chapter is dedicated to the memory of Dr. Michael J. Goldstein, colleague, mentor, and friend, who devoted his career to improving our understanding and treatment of schizophrenia through his research and encouragement of young investigators.

6.01.1 INTRODUCTION

> Patients come to psychotherapy because they are demoralized by the menacing meanings of their symptoms. The psychotherapist collaborates with the patient in formulating a plausible story that makes the meanings of the symptoms more benign and provides procedures for combatting them, thereby enabling the patient to regain his morale. (Frank, 1986)

Although not all therapists would be happy with the idea that they are "formulating a plausible story," the process of clinical formulation remains the lynch pin that holds theory and practice together. This is agreed by proponents of most major therapeutic traditions: for example, behavior therapy (Turkat & Maisto, 1985; Wolpe & Turkat, 1985), psychodynamic therapy (Barber & Crits-Christoph, 1993; Perry, Cooper, & Michels, 1987; Silberschatz, Fretter, & Curtis, 1986), family therapy (Minuchin, 1974), cognitive therapy (Freeman, 1992; Persons, 1989, 1993), cognitive analytic therapy (Ryle, 1978, 1990), and interpersonal therapy (Klerman, Weissman, Rounsaville, & Chevron, 1984). The attempt to construct and use a clinical formulation is central to the work of therapy. Various methods for systematizing the processes involved have recently been proposed (Horowitz, 1989; Luborsky & Crits-Christoph, 1990) and, thinking specifically about the issues involved in psychotherapy integration, Goldfried (1995) has put forward a case for developing a common language for case formulation that is independent of theoretical orientation. Personal discussions of many kinds may be more or less valued and helpful to someone experiencing a difficulty, including the informal advice traded between friends, but one of the major differences between informal discussions and responsible clinical practice is that they do not make use of the process of formulation. The attempt to formulate a case, so as to apply an appropriately chosen method of intervention in the light of a particular theory, is one of the activities that makes therapists, as opposed to friends, accountable for their practice.

This chapter discusses issues concerning clinical formulation that are relevant to therapists from different theoretical backgrounds. However, the illustrations of the general points made will largely be drawn from the author's own experience and will therefore reflect the author's original cognitive-behavioral training, together with a more recent interest in exploring possibilities for integration between different kinds of psychotherapy.

6.01.2 DEFINITIONS: WHAT IS A FORMULATION?

6.01.2.1 Main Principles

A formulation is the tool used by clinicians to relate theory to practice. Clinicians use theoretical as well as practical knowledge to guide their thinking about the problems and difficulties presented by the people who come to them for help, and this combination of ideas helps them decide how best to help those people. However, although the theories are relatively simple and clear—admittedly to varying degrees—the information brought to treatment, and gathered during the process of assessment, is always complex and often unclear. The process of marrying theory and practice is therefore fraught with difficulty. As well as having different reasons for requesting psychological help, people vary in their ability to describe or name their difficulties, in their histories and relationships with their families, friends and colleagues, in their ability to relate to a therapist, degree of psychological-mindedness, and emotional expressiveness. As well as having different theories, training, and clinical experience, therapists vary in the ways in which they understand, communicate with, and relate to their patients. Therapists bring with them to therapy specific skills, expertise, and information, and also their individual personalities and inclinations. The process of formulation is influenced by all these disparate factors, and this makes learning how to formulate a case with the necessary objectivity, clarity, and attention to the individual to guide a successful treatment one of the most fascinating, rewarding, and difficult tasks faced by clinicians.

The assumption that many clinicians of different orientations probably share about the psychological difficulties of others is this: at some level it all makes sense. Even though our understanding of the processes involved, and particularly of their inter-relationships, is incomplete, this assumption was given a simple, and relatively uncontroversial, diagrammatic form by Padesky and Mooney (1990). The difficulties that people describe to their therapists have four inter-related aspects (cognitive, affective, behavioral, and physiological), and change in any one of these variables affects all of the others, as shown by the bidirectional arrows in Figure 1. So, taking anxiolytic medication can make one feel calmer, think about problems more constructively, and do some of the things that previously seemed too difficult or overwhelming. Feeling more cheerful can lighten ones step, help one to feel more optimistic, and relate more productively to others. Changing ones perspective—or way of thinking—can provide the sort of new outlook that helps to dissipate distress, reduce tension, and encourage constructive activity, and so on. The four ways in which aspects of psychological life are conventionally categorized reflect the internal workings and psychological state of a person at a particular point in time. This person is at the same time relating to the external world through a personal social, political, and historical context. The factors that determine this context, and fashioned it to be the way that it now is, are not easy for psychological therapists to know about: hypotheses for explaining and understanding the way they interact with each of the four types of phenomena have been made. The overall configuration is the source of the narrative, or story, that a person brings to therapy. If we understood the rules governing the relationships between all these factors we would, no doubt, be better able to help our patients.

The business of therapy, to a large extent, involves intervening to facilitate change in (at least) one of the four main aspects of psychological life shown in Figure 1, and different kinds of therapy attend differently to these different aspects, entering the process of change through different gateways. The intention, however, is much the same—to help people solve the problem or problems that they bring to therapy. Pharmacological and traditional behavioral therapies provide perhaps the clearest examples as the methods that they use, and the formulations upon which these methods are based, can be isolated relatively easily. Cognitive therapies, which adopt both cognitive and behavioral methods, operate on at least two levels. They may concentrate on identifying and reexamining particular thoughts, thereby changing feelings and behavior, and/or they may focus on underlying meanings and beliefs and adopt more sophisticated and complex methods of intervention, often related to those used in more dynamic and experiential traditions. Experiential therapies make specialized use of the medium provided by the feelings and thoughts arising in the present context of therapy, and work with these to facilitate a dynamic process of change. In order to do this, it becomes essential to think about, and to formulate, what happens in the relationship between the two people involved in therapy—methods which were originally described and understood by proponents of the various psychodynamic schools of therapy. Interpersonal therapy and systems therapy also formulate problems in terms of relationships between the person requesting help and others around them, and use this understanding to help people change as they wish. All of these methods initiate the process of change in different ways, determined by the way in which they understand, or formulate, the problem presented, and it is this understanding that determines what therapists do—what steps they take to alleviate the problem.

The point is that the way in which a formulation is constructed will be influenced by the point at which a therapist enters, and attempts to influence, this dynamic relationship between these main aspects of psychological life. Some general points are important:

(i) each aspect influences all of the others, so none of the therapies has the exclusive aim of changing one factor. Rather, by focusing the process of change in one place, the aim is to bring about the change that the patient desires—usually to "feel better," in all the relevant respects.

(ii) The main medium of therapy is language—what one person says or suggests, to another. To this extent, the cognitive, implicational context within which therapies take place provides the basis for the way in which the presenting problems will be formulated.

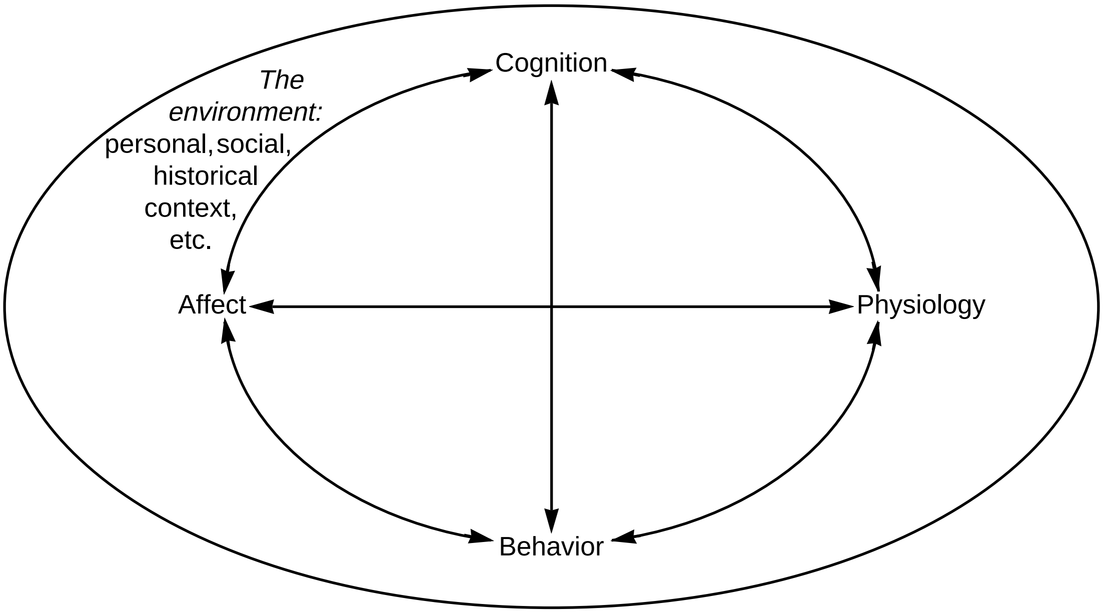

Figure 1 Inter-relationships between aspects of functioning (Padesky & Mooney, 1990).

(iii) Understanding of other people, and hence the ability accurately to formulate their problems, develops within the context of the relationship between them, mediated by factors such as trust and acceptance as well as by language.

(iv) Our understanding of the ways in which the aspects of psychological life are integrated is partial. At this point in time, psychology is an imperfect but developing science. The implication of this is that formulations for the purpose of therapy have to be speculative.

Formulations can best be understood as hypotheses to be tested, and the most obvious, if not the most logical, test of a formulation will be the response to the selected interventions. This is not to say that an expected change following a specific intervention proves that the formulation on which it was based is accurate. Unfortunately, the reasons why change occurs are far more complex and difficult to discern than this. However, the formulation used in this way is perhaps the main tool that the therapist has from which to draw such conclusions in the individual case. Thus, working in an open-minded way with a formulation provides a means of contributing as a therapist to the scientific endeavor involved in finding out which are the best, most effective, and most efficient, methods of treatment.

Although a formulation provides the link between theory and practice, it does so at a different level of generality. A theory is the source of general explanations and general hypotheses, whereas a formulation is specific to the person to whom it applies, and therefore is the source of more specific explanations and hypotheses. The specificity of the formulation is the source of ideas about the selection of specific interventions and about how to adapt them for use with a particular person. It is for these reasons that Wolpe and Turkat (1985) describe a formulation as a theoretically guided way of structuring the information concerning a patient's problem. It reflects the product of taking an individual approach to clinical phenomena and combining this with knowledge of relevant theories, scientific principles, and research findings. It involves imposing an explanatory system upon the material presented, and raises questions concerning the degree to which this explanatory system should reflect every aspect of a problem. One view is that it should reflect everything, including a patient's past development, characteristic ways of behaving and forming relationships, emotions, beliefs, assumptions, attitudes, self-evaluations, expectations, attributions, appraisals, and so on. In practice, the degree of elaboration required depends upon the purpose for which the formulation is made. At this point it is probably sufficient to enunciate one of the principles that will run through this chapter—that of parsimony. In principle, it is always better, and more useful, to keep the formulation as simple as possible. The temptation to elaborate a formulation is strong, especially when dealing with complex cases. However, the simpler and clearer it is the more readily will its implications be seen and the easier it will be to use.

Theoretically speaking, the principles that guide the practice of formulation are derived from the way in which the concept is defined. The three main ones to be proposed here are:

(i) A formulation should be based on a theory, reflecting an attempt to put the theory into practice.

(ii) A formulation should be hypothetical in nature, so that it can be modified by information gained during the course of treatment.

(iii) A formulation should be as parsimonious as possible.

6.01.2.2 Formulation and Diagnosis: Assumptions

In psychological practice there appears to be a common assumption that only those patients who participate in research trials have simple diagnoses, for example, of the kinds defined in the various versions of the *DSM*. Diagnostic systems are useful for ensuring that the populations studied in different places are similar in the relevant respects, and they are useful for insurance purposes, but from the point of view of the therapist they have limitations in that they rarely provide specific implications for treatment. Besides, unselected samples of patients often do not have single, clear problems—indeed informally they are commonly said to "fulfill criteria for an average of 2.3 diagnoses." A formulation, however, is designed precisely to fit the individual and is intended to help therapists to derive theoretically-based hypotheses about factors that contribute to causing and maintaining their specific problems—to explain as well as to describe. Therefore, the argument runs, diagnoses are less useful than formulations, from which specific treatment implications can be derived, and they may be less necessary than formulations. For example, one depressed person's sense of failure may be triggered by an inability to live up to exacting standards and another person's by an inability to form close relationships (for any number of reasons, which may be discovered during therapy and included in the formulation). Only having the diagnosis tells the therapist nothing about this difference, and ignoring the difference will reduce the chances of achieving a satisfactory outcome.

This argument has much to recommend it to the therapist, especially as diagnoses are largely atheoretical descriptions, and therapists can use their theoretical knowledge to construct formulations that are clinically useful. This does not mean thinking anew with each patient, but keeping in close touch with theoretical and clinical research so that, for example, empirically validated treatments can be selected when the diagnosis suggests they would be appropriate, and individual formulations then used to specify details of their application. Learning to work with a formulation instead of relying on a diagnosis also has advantages when the problems presented are unusually rare or complex and do not fit readily into a diagnostic system, or when the system does not succeed in "carving nature at the joints," and the demarcation between one diagnosis and another is difficult to establish. Of course there are difficulties with this point of view. Seen from the patient's perspective, over-reliance on the process of formulation may involve a degree of risk.

What if the theory is wrong? Or if the therapist is unclear about it? Or susceptible to bias? Or unable to come up with an adequate formulation? Or attempts to combine one theory with another without understanding sufficiently well the implications of doing so—as when borrowing from experiential or dynamic ideas when doing cognitive therapy for instance? This risk can be reduced by formalizing the requirements of responsible clinical practice—by providing adequate training and supervision, by clarifying ethical guidelines, and by defining criteria for professional accountability, including the expectation that practitioners will keep in touch with the literature relevant to their practice. Ultimately though, the mysterious faculty of clinical judgment has also to be brought into play. Without this—whatever it is—clinicians may well run into difficulties, both making and using formulations.

The implication of this argument is primarily that, much of the time, formulations are more useful than diagnoses, provided that therapists are well versed in the theories they are using, and that diagnoses, which can after all convey a large amount of information in a few words, may help to streamline the process of assessment, and may guide decisions about treatment in relatively straightforward cases. For example, knowing someone is socially phobic directs attention towards a fear of being humiliated or embarrassed, and knowing the diagnosis is of bulimia nervosa focuses attention on over-concern with shape and weight (among other things). Underlying problems of self-consciousness and poor self-esteem may be relevant in both cases, so the assessment which provides an adequate basis for a formulation, and for a specific treatment plan, must cover more than the criteria for inclusion and exclusion that determine whether or not someone qualifies for a diagnosis.

6.01.2.3 Formulation and Diagnosis: Controversial Issues

The assumption behind the argument presented above is that a treatment plan based on a formulation will have a better chance of success than one based on a diagnosis. However, there is considerable debate about this issue, and some recent research suggests that the assumption could be false. Schulte, Künzel, Pepping, and Schulte-Bahrenberg (1992) and Schulte (1997) found that patients with phobias, assigned to a standardized treatment (exposure *in vivo*) on the basis of their diagnoses, responded at least as well as, and possibly better than, patients whose treatments had been selected on the basis of individual problem analyses. With this finding in mind, Wilson (1996, 1997) summarized the arguments for using manual-based, empirically-validated treatments, also selected on the basis of diagnoses, and argued that there are inherent limitations involved in basing treatment on idiographic case formulation. As he points out, making formulations involves making judgments and judgments are fallible. They are demonstrably susceptible to bias and using them introduces an additional source of error. It would be better, he argues, to adopt an actuarial approach to assessment and treatment as this is more likely to result in a superior outcome than using clinical judgment, at least when treatment manuals are available.

The issue is complex (Beutler, Williams, Wakefield & Entwistle 1995; Hayes, Follette, Risley, Dawes & Grady, 1995; Norcross, Alford, & DeMichele, 1992; Seligman, 1995; Stricker & Trierweiler, 1995), and differences will not be settled here. Nevertheless, it is useful to clarify the basis of the disagreement, as two issues are frequently confounded. The first concerns the failure of practicing clinicians to adopt standardized practices and the second concerns the dangers of over-reliance on individual formulations. Those who argue against the use of formulations seem to forget that it is the job of practicing clinicians to bridge the gap between science and practice, and in doing so to balance the requirements of recommended procedures with clinical flexibility. A formulation, as defined above, is intended to facilitate this process—to assist the clinician in adapting the procedure to the particular circumstances. When treatments so adapted are reported to be less effective than expected, then many factors in addition to formulation could contribute to this finding. These include the quality, integrity, structure, and delivery of the treatment, the accuracy with which the effects of treatment can be measured, and the relevance of the measures used to the outcome desired by the patient. Proponents of the view that treatments can be selected on the basis of diagnoses alone seem to assume that case formulation is idiographic, in the sense that making one is unconstrained by theoretical ideas and using it to select interventions is independent of the findings of clinical research.

Neither of these points is accepted here. Instead it is argued that individual case formulation is always relevant, even when applying a manual-based treatment (examples will be found below). It is also argued that formulations have to be rooted in theory to be useful, and that using clinical judgment is not providing a licence for subjectivity, but recognizing that at least some of the time clinicians will not be able to follow the rule book, even when there is one. Then they have to use their judgment. In doing so, they can appeal to many sources of understanding, including theories about psychological dysfunction, and their knowledge of the relevant literature. As Stricker and Trierweiler (1995, p. 997) put it "it is likely that the practitioner always will be required to go beyond firm and available scientific knowledge"—less so when treating phobias than when treating a complex of depression and anxiety in someone with a dependent personality type, and not without keeping in touch with scientific advance—but individual judgment and case formulation remain indispensable clinical tools. Using these tools does not exempt the practitioner from being aware of the pitfalls of basing decisions about treatment on anecdotal case material, intuition, or subjective impression. On the contrary, working with a formulation that can be explained to others provides a check on the use of too much speculation and too many far-fetched inferences.

Therapists need to speak about their patients' problems in many settings and contexts, and to do so can make use of any of the available systems—labels, diagnoses, descriptions, and formulations. Labels (e.g., manipulative, hysterical, narcissistic, personality disordered) are efficient but can bring assumptions with them (and in these examples, assumptions that may not be to the advantage of the person being labeled). Diagnoses reflect agreed systems of categorization and for the most part are based on particular kinds of descriptions rather than on theories. They may or may not be subject to the same disadvantages as labels. Formulations differ in that they bring together the products of theoretical knowledge and clinical judgment. Their theoretical basis reflects ideas about the factors that cause and maintain problems, and that precipitate or prolong particular episodes of distress. This theoretical basis provides a framework for the type of personal, individual formulation on which precise decisions about treatment can be based. Their advantages and disadvantages are discussed further below.

6.01.2.4 The Difference Between a Formulation and a Model

Models are ways of conceptualizing particular disorders (e.g., the cognitive hypotheses of obsessive-compulsive disorder and of health anxiety described by Salkovskis (1996), or of formulating particular patterns of functioning (e.g., the role–relationship models developed by Horowitz, Eells, Singer and Salovey (1995) or the functional analytic causal model of Haynes, Uchigakiuchi, Meyer, Orimoto, and Blaine (1993). Models, as understood here, are constructed from a particular perspective, so there are separate cognitive models of panic disorder (Clark, 1988) and social phobia (Clark & Wells, 1995), and the psychopharmacological or interpersonal psychotherapy models of panic disorder differ from the cognitive model. These differences are valuable in that they stimulate useful research, as well as the development of sets of coherent treatment strategies. Using the cognitive model of panic disorder as an example, this would suggest that catastrophic misinterpretation of bodily symptoms plays a crucial role in triggering panic attacks, and that understanding this will help people who suffer from panic disorder to identify the symptoms that trigger their panics. They will then be in a position to think again about the meaning of these symptoms, and to reinterpret them in terms of (harmless but distressing) panic rather than of real, impending catastrophe. In order to facilitate the therapeutic process, the model has to be translated into a conceptualization (or formulation), and structured systems for doing this can be developed, as in this case has been done by Dattilio (1994). So the model provides guidelines for an individual formulation which encourages a new explanation—the leap in my heart could be a response to the coffee I have just drunk, or a normal arrhythmia that I notice more readily than I used to because it frightens me, and not a sign of imminent cardiac crisis.

Although a model has implications for treatment, it differs from a formulation in that it operates at a different level of generality, and has a different content. So, the way in which a formulation applies to particular people will depend upon their personal history and circumstances. One person's panic may be triggered by leaps in the heart and another's by losing concentration when being spoken to (and a third may find that memories of traumatic incidents, flashbacks, or nightmares precipitate panic, possibly because they trigger associated sensations that then trigger the panic attacks). There will in practice always be exceptions to the rule, cases in which, for example, no sensational trigger can be identified. Then the clinician may be best advised to base the formulation on a higher level theory rather than on the specific model—in this case on the general theory that cognitions, including meanings, are closely related to feelings and behavior, and that changing one is likely to change the others. Thus the formulation illustrates, in ways that are clinically relevant, how the model applies, and does not apply, to the case. It assists the therapist in looking for particular theoretical constructs or processes (catastrophic misinterpretations in this example), and also in making a judgment about the degree to which the case is typical.

Atypical cases arise when patients have more than one difficulty—social anxiety as well as panic disorder for example—or when they have especially complex or rare problems such as panic attacks in the context of avoidant or borderline personality disorder. Then, conceptually speaking, it may be more useful to draw on more than one model to construct a single formulation, or to look for models with a higher order of generality. Writing about psychodynamic formulation, Perry et al. (1987) point out that overlapping models of mental functioning may emphasize different aspects of development and psychopathology. They distinguish ego-psychological, self-psychological, and object relations models, and make the important point that a certain amount of trial and error may be needed in constructing a formulation that explains the presenting data: "the absence of a meta-model to explain all data makes this trial and error unavoidable" (p. 546). What clinicians are looking for in a formulation is a way of explaining and understanding the relationship between a patients' inner lives and their outer lives that is the product of their personal history, explains present difficulties, and guides future therapy. Their sources in this search include knowledge of diagnostic systems, of relevant theoretical models, and of outcome research, as well as information about the individual case—otherwise they would have to reinvent the wheel each time.

6.01.2.5 Types of Formulation

Typically, different therapeutic schools are thought to use different types of formulation. In general, behavioral and cognitive therapies make use of more mechanistic formulations, based on theories about learning and detailed functional analysis (Hayes & Follette, 1992), or on theories about processes such as the supposedly circular relationships between thoughts and feelings, and more dynamic therapies employ more narrative-based formulations, placing current problems in the context of a developmental history. Some systemic and experiential approaches to therapy adopt a third, essentially dynamic, approach, claiming that formulations have constantly to be re-formed in the present, as therapy focuses on moment-to-moment events (Goldman & Greenberg, 1997). They also point out that the process of formulation can be dangerous and limiting when it makes use of preset categories and ideas. A constantly changing situation then appears to be fixed, and opportunities for change may be obscured (Eells, 1996; Rosenbaum, 1996). However, the process of formulation is still thought to be essential, and its main purpose is still to look for patterns and links that assist in understanding, and to provide ideas about how to bring about change. So, distinctions can be applied too rigidly. The developmental history of a problem or a person, or the narrative, is always relevant (Nicholson, 1995; White, 1989), although it may be understood in different ways, and so are ideas about the mechanisms that precipitate an episode of distress or perpetuate a problem. Overt differences between types of formulation are therefore relatively unimportant to an understanding of the term, and of the functions that the activity of formulating a case performs for the therapist.

6.01.2.6 Levels of Formulation

When making a formulation, it is necessary to think at many different levels, and the number of levels postulated obviously varies with the theory being applied. Taking an example from cognitive-behavioural therapy (CBT) to illustrate the point, at the most superficial level, or the level of "overt difficulties" (Persons, 1989), the main task is to define the problems and the ways in which they are maintained, usually in terms of vicious cycles. Someone who feels depressed may withdraw from company, think about being all alone, and become increasingly depressed. Even such a simple formulation suggests a focus for intervention—working to reduce the withdrawal. Thinking about the factors that precipitated the depression adds another level to the formulation. The person might have become depressed when their job required them to move to a new place, when they got divorced, or when their children left home—factors that would demand different types of adaptation, to be promoted by the therapist in different ways. Stressors are additive, so many factors may be involved, and an apparently minor stressor may be the straw that broke the camel's back (and relatively irrelevant to the formulation), or it may reflect a particular personal vulnerability. Factors that predispose someone to become depressed, biological as well as psychological factors, add a further level, and the way in which these are understood, and formulated, will again influence the selection of interventions. At the most profound level of all, assuming that "at some level it all makes sense," the formulation is supposedly capable of reflecting the meaning of structures through which people interpret and think about, remember and recount, their experiences, and theoretical assumptions about the origin of these things.

This is the standard way in which psychiatric formulations have traditionally been made—in terms mainly of predisposing, precipitating, and perpetuating factors. However, there are yet other levels to consider, reflecting social, cultural, and historical factors. Social assumptions ("men should not show their feelings" or "women are bad organizers") influence the views of therapists as well as patients, and cultural assumptions may or may not be shared between therapist and patient. Some cultures, for example, do not share the common Western therapeutic goal of autonomy, especially for women. Others assume that a relationship between a professional person and their client is one involving activity—or authoritative pronouncements—on the one side, and passivity—or receptivity—on the other. In addition, different hierarchies of values can interfere profoundly with the therapeutic process. An example in our culture is when someone thinks it more important to avoid giving offence than it is to tell the truth. Although it is never possible to stand outside all of these factors, making a formulation helps therapists to think about them, to identify them clearly, and to become aware of their potential influence on the interpretation of other people's circumstances. It can help therapists to ensure that the ways in which they understand problems and select interventions are not influenced by unwanted biases. Seen in this way, a formulation assists therapists in achieving a relatively objective stance.

Formulations are always made from a particular perspective—in the author's case made (usually) from a cognitive-behavioral perspective, and from that of a White woman of a certain age, living in Britain now, whose ways of thinking have been formed by her own learning and experience. A formulation is neither about fitting information about a patient to a predetermined formula, whether that formula be derived from a general theory or from a more specific model, nor is it a personal judgment, though both things are relevant. It is about developing the kind of understanding of another person, their circumstances and their difficulties, that enables a therapist to apply the theoretical knowledge acquired during training to help that person. There is no single right way of making a formulation. The general aim is to map the territory so that one can then explore the possibilities for change, and not to let these be influenced by factors that are irrelevant to, or unwanted by, the person who is receiving help.

6.01.3 PURPOSES: WHAT A FORMULATION IS FOR

One common view of the purpose of formulation is that it is for explaining the past, making sense of the present, and suggesting what to modify in order to influence the future. It can also be an important means of communicating understanding, either to the patient or to another professional, whether in the role of supervisor or colleague. However, its prime purpose is to help therapists to apply the theory they have learned to their practice (a comprehensive account of different approaches to formulation is given by Eells (1997).

In practice, there are many answers to the question "What is a formulation for?" The main functions of formulation are listed in Table 1. The main point is that making formulations is an essential, and not an optional, element of the therapeutic process. Formulations do not have to be 100% accurate or complete in order to be useful precisely because they provide a source of testable hypotheses. They can be changed when they turn out to be wrong—and nothing is lost by using a partial or partially mistaken formulation which can be improved and corrected as the process of therapy continues, and reveals the initial mistake. They guide questioning, and open the therapist's mind to the kind of understanding from which effective treatment strategies can be derived, applied, and evaluated. Therefore, the author would argue, that therapists should work with a formulation in mind right from the start. Ideas about people and their problems cannot be kept at bay or excluded, even when first meeting them or reading a referral letter about them. One way of trying to ensure that this information is openly received and accurately assessed is to engage immediately in the process of formulation—in applying both theoretical and clinical knowledge to the particular case. Just as when first visiting a new place, a rough sketch map may set one on the right road at first, but will need expanding and revising if it is to guide more detailed exploration.

6.01.3.1 Understanding: The Overall Picture or Map

A formulation "provides the map of the territory and once you have that you can use whatever vehicle you are most comfortable with" (Beck, 1991). Formulations, just like maps, provide an overall view (often in diagrammatic, conventional form) of something that it is not possible to see directly all at once—the wood as well as the trees. They indicate which are the important features, their size and shape, and the way in which they relate to each other. Mapping the territory is clearly the product of accurate assessment (see Section 6.01.4), and formulating enables therapists to make and to justify such statements as "this lack of energy is part of the depression," or "in this case the anxiety seems to be primary and the depression secondary." Similarly, formulations can indicate where information is missing and prompt appropriate questions: where did this low self-esteem come from? Why does it become apparent in the context of close personal relationships but not at work?

6.01.3.2 Prioritizing Issues and Problems

An overall formulation helps to differentiate what is essential from what is secondary in a general sense. It also helps in a more particular way to decide which issues or problems should be prioritized. Someone who believes that they cannot change is unlikely to remain engaged in therapy unless they can see the point of it. Creating hope, or the context for a developing relationship—something with a future, in which change is inherent and undeniable—then becomes a priority. Likewise, an initial assessment may indicate primarily that inability to trust people will make it hard to disclose distressing material, and building trust within the therapeutic relationship is necessary before a more detailed and accurate formulation can be made.

It is probably not unusual for patients and therapists to start the process of therapy with somewhat different priorities. Usually this problem can be overcome during assessment and those early stages of therapy during which goals become clear or are specifically agreed. But sometimes different priorities persist, and then the process of re-formulating can help to solve the problem. For example, an anxious and hypochondriacal patient who was worried, among other things, about seeing "floaters" in his visual field, started to respond well to treatment that was formulated in terms of his underlying sense of vulnerability. The formulation reflected the way in which his various concerns made him feel threatened, and think that he was at risk for being unable to handle a number of initially rather vaguely specified distressing eventualities. However, although his confidence increased, his distress about the floaters did not diminish. If anything it increased, in tune, it must be acknowledged, with the therapist's frustration when discussing this issue became his main priority. Focusing the work of one session on the meaning or understanding of this problem revealed (for reasons which later became clear) that visual anomalies for this person felt, in his words, "like a bereavement." Formulating this aspect of the problem in terms of loss rather than in terms of vulnerability changed the focus of treatment, which then became more productive. This example also illustrates how characteristics of the process of therapy can contribute to ideas about the formulation, especially in those cases in which change is not proceeding as well as might otherwise be expected.

Table 1 Summary of the purposes of formulation.

Clarifying hypotheses and questions
Understanding; providing an overall picture or map
Prioritizing issues and problems
Planning treatment strategies
Selecting specific interventions
Predicting responses to strategies and interventions; predicting difficulties
Determining criteria for successful outcome
Thinking about lack of progress; trouble shooting
Overcoming bias

6.01.3.3 Planning and Selecting Intervention Strategies

Once a hypothesis about how the presenting problem can be understood has been formulated, the most important functions of a formulation are in planning a treatment strategy and selecting appropriate methods of intervention. Persons (1989) provides some lucid examples: someone who avoids exercise because they are bad at time management, scheduling, or self-organization has a different problem to overcome, and needs to acquire different skills from the person who avoids exercise because they are embarrassed about their appearance; insomnia that is associated with the fear of letting go may require different interventions from insomnia that results from overcommitment.

The way in which a problem is formulated thus determines what should be done about it (Blackburn & Twaddle, 1996; Butler & Low, 1994; Eells, 1997). If avoidance maintains the problem, then facing the fear is likely to reduce it, and in individual cases the formulation helps to specify idiosyncratic aspects of the avoidance (the spider phobic who will not walk under trees; the social phobic who is more fearful of silence than of conversation). The general vicious cycle model is common to both—and indeed, a standardized method of treatment of proven effectiveness, exposure *in vivo*, is readily available. The individual formulation is still necessary because it specifies exactly what steps to encourage the person to take.

Planning overall strategies is just as important a product of formulation as the selection of specific methods of intervention, but is a more complex task, and requires of the therapist more than one level of understanding. The way in which depression or anxiety is understood may suggest, for instance, that it would be helpful to increase levels of activity before discussing thoughts associated with depression; or to build up a repertoire of coping skills before facing fears. Many such imprecations are based on clinical judgment (or clinical intuition) as much as on theoretical or experimental work, and in these cases it is especially important that they should be made clear by means of a formulation. For example, it is often said that when working with people who have suffered abusive experiences in childhood, one should help them to develop a variety of support systems, ways of dealing with intense feelings or suicidal impulses and of creating around themselves a sense of safety, before exploring memories of early traumatic experiences, and the meanings of such events, in depth.

Clearly, this overall strategy reveals assumptions about how the effects of these events can be understood, about the effects of talking about them, and the interventions used—assumptions which formulations clarify, and which are potentially amenable to research, but which will differ according to the therapist's theoretical orientation. A secondary purpose of clarifying the formulation and its function in selecting strategies and interventions is to facilitate evaluation of interventions.

6.01.3.4 Predicting Responses and Difficulties

Because a formulation reflects theoretical assumptions, it helps therapists make two kinds of predictions that are essential in therapy: to predict the effect of the intervention, assuming it is successfully applied, and to predict the stumbling blocks and difficulties that will be encountered during therapy. An anxious person treated during a clinical research trial (Butler, Fennell, Robson, & Gelder, 1991) held the belief that "all my ideas are bound to be wrong." She became more confident as she learned to identify her ideas, to act upon them, and consciously to evaluate the consequences of doing so. Her formulation enabled us to predict first that she would feel especially vulnerable and be likely to overgeneralize and catastrophize the consequences when she made mistakes, and second, that she was likely to find it especially difficult to apply the new strategy when relating to her partner, but easier to build up the necessary skills (and courage), and to increase her confidence, in the context of other relationships (including ours). Treatment in this case was guided by the requirements of a treatment manual, and the example illustrates the important role played by clinical formulation in the application of standardized treatments.

It is probably true to say that interpersonal difficulties are one of the most common sources both of patients' problems and of problems encountered during psychological therapy; for example, an ability to form superficial relationships without being able to sustain deeper friendships, or veering between passivity and aggression when interacting closely with others. Such difficulties also play their part within the therapeutic relationship, and they are much more easily dealt with if the processes involved have been understood in terms of the theory being used, and problems predicted in advance. Formulating helps people to recognize such patterns, to develop hypotheses about their origins, functions and effects, and to think about whether and how to engage in a process of change.

6.01.3.5 Determining Criteria for Successful Outcome

Theoretically a formulation provides the basis for hypotheses about what needs to change for someone to feel better, or the goals of therapy in the broad sense of the term. This is obvious when a theoretical model for the condition being treated is available, but the point applies more generally as well. The present version of the cognitive model of social phobia (Clark & Wells, 1995), for example, suggests that self-awareness, or self-focused attention, plays a central role in the disorder. In outline, when in a socially frightening situation a social phobic feels self-conscious, notices symptoms of anxiety and tries to keep safe. An individual formulation based on this model would specify the way in which this actually happens. For example, when speaking to others (e.g., colleagues during a lunch break), Marie became aware of the sound of her own voice, felt anxious, flustered, hot, and shaky, and found it hard to listen to what was being said. She thought other people must be able to see how nervous she felt and tried to fade into the background as quickly as possible (keeping herself safe by avoiding eye contact, saying little, speaking in a quiet voice). Both general and specific goals for change can be derived from thinking along these lines. In simple terms, if Marie can focus her attention outside herself, and listen without self-criticism to those around her, if she can reverse the safety behaviors (make appropriate eye contact, speak more audibly, move around freely), she will break the cycle and start to feel less anxious. The general criteria for change are reflected in the three elements of the model specified here, the self-awareness, safety behaviors, and symptoms of anxiety, and specific ones reflect the individual ways in which these factors are manifested in the case of Marie.

Of course this might not be the whole story. Marie's social anxiety may be based on a belief in her own unworthiness relative to others, and reflect an unhappy history of family relationships. Such formulations again indicate criteria for change—a sense of worthiness or the ability to form more satisfying relationships in the present. The difficulty here is that more abstract and general phenomena are harder to identify, define with any precision, and measure than more superficial and specific ones. Criteria for change are therefore more easily derived from formulations at lower than at higher levels of abstraction, and indeed the more specific the formulation the easier it will be to be clear about what exactly needs to change.

6.01.3.6 Thinking About Lack of Progress

There are many possible reasons for lack of progress in therapy, including working without making a formulation. The first line of defence when this happens must be to formulate or to reformulate the problem. The way in which this is done will have specific implications for the next steps in therapy. For example, if the problem is a long-standing, chronic one, it may be that much practice is needed and that it is unrealistic to expect faster change, in which case it may be important to think about how to keep the momentum of change going—about how to maintain hope and create the energy for change when doing so is difficult. If the original formulation was inaccurate or incomplete, the failure to change may suggest that different strategies and interventions are needed. When lack of progress leads to frustration, and the reactions of both the patient and the therapist interfere with subsequent progress, including these factors in the reformulation can reveal ways of overcoming them. Blocks in treatment are nearly always informative and formulation skills should be used to identify their specific nature.

Often this is complex and involves making hypotheses about past events, the exact nature of which can never be known. Possible formulations in these circumstances, often derived from a combination of observation and understanding of the apparent effects of the past on the present, can suggest which avenues to explore so as to make further progress. For example, a patient who provided a cold and dispassionate account of a childhood in which she was neglected, often frightened and sometimes threatened with physical abuse, appeared to have developed a variety of ways of controlling both the experience and the expression of her emotions. Many, but by no means all, of these ways were dysfunctional. A possible formulation of this case suggests that improvement will remain blocked unless or until she becomes able to experience and express the relevant feelings. Doing this is likely in the first instance, to precipitate periods of distress, and the precise implications for therapy to be derived from it will depend on both the skill and the emotional sensitivity of the therapist as well as on a willingness to adapt the formulation according to what happens.

Drawing these points together, it is clear that formulations cannot be treated as a matter of last resort, only to be constructed and worked on when the going gets difficult, when dealing with chronic problems, when treatment has apparently gone on too long, or when preparing to report to someone else. Formulations do not provide the answers to questions, but a rich source of questions and ideas of potential therapeutic value. They should not become the tool for applying a preconceived theoretical plan to someone for whom the plan does not fit, nor should they focus exclusively on someone's problems and difficulties. Accurate formulation takes account of a person's strengths as well as failures, talents and potential, as well as shortcomings and failures.

If formulations can be so useful it is surprising that so little attention has been devoted to them both within training programs and in the literature. One reason for this may be that formulations were supposed to follow logically from the processes of assessment and functional analysis, and additional skills were not often specified. A more important one is probably that formulating is difficult. As already indicated, in practice it involves exercising clinical judgment as well as the ability to relate theory to practice. Also, until recently, there was less communication between people with different theoretical backgrounds, and fewer challenges to think about alternative methods of formulating specific cases. So, the next important question is "How do you construct a formulation?"

6.01.4 METHODS: HOW TO CONSTRUCT A FORMULATION

The main reason for considering the purposes of formulation before thinking about how it should be done is that there is no single correct method—how you do it is in general determined by understanding the purposes that it serves, and in particular by the theoretical orientation of the therapist. The end product should enable the therapist to relate theory to practice in a way that can direct and inform the process of therapy, and the methods used vary enormously. For the student this is both confusing and liberating, as it demands creativity and the ability to deal with abstractions as well as the more mundane skills primarily involved in assessment. Assessment is a necessary step in the development of a formulation, but it is not a sufficient condition for it. Unfortunately, it is possible to assess, in the data collection sense, without developing a formulation.

6.01.4.1 Sources of Information

An account of presenting problems, informed by knowledge of psychological processes and diagnostic systems, provides a common starting point, and assessment covers all of the four aspects of functioning illustrated in Figure 1 and their determinants: cognition (thoughts, assumptions, attitudes, beliefs, images, etc.); affect, behavior, and physiological sensation; the present context for the ways in which these things are manifested; and an account of their background and associated developmental history. It also draws on information gathered during the process of referral, such as a summary of the problems as understood by the referrer, of the reasons for requesting help and of responses to treatment received so far, and on the impressions and observations made during the first encounter with the therapist when the processes of mutual interaction are set in motion.

Therapists use many skills in helping them to understand this material: theoretical knowledge; products of academic learning and professional training; and clinical judgment. The process of encapsulating this understanding in a formulation, which at first takes time and becomes quicker with practice, is facilitated by adopting a questioning stance. The aim would be to be able adequately to answer three of the key questions that patients ask: Why me? Why now? What keeps it going? and in doing so it helps to draw on a further set of questions central to the process of formulation, which therapists can pose either to themselves or to their patients: How do you understand that (or make sense of it)? What do you think is going on? How does this all fit together? What might be the missing links? What does that mean about you now? Is there a pattern here?

Formulations are useful in helping people to think again about their difficulties, and see them in a new (e.g., clearer, more realistic, or more illuminating) light, and the process of assessment potentially reveals the patient's present point of view. In order to develop an understanding of such personal and unique phenomena, it is particularly useful to pay attention to the ways in which people react to their experiences. Their comments provide a rich source of such information—"I have to keep control" or "I need to know I am succeeding" are remarks that suggest hypotheses about the self and about underlying processes and mechanisms. Ideas expressed about others, such as "she'll be miserable alone" may fit with assumptions that precipitate or maintain presenting problems. General comments of the kind "you have to conform or you can't get on" reveal attitudes that may (or may not) dominate within the real world in which the person lives. Expectations about the future, including those about the process and outcome of therapy, are also revealing: "I won't be able to do what is needed," "There are some things I would rather not talk about," "I'm relying on you to make me better." In order to formulate, it is important to understand the personal significance of experiences as well as their phenomenology. These comments illustrate well how the processes of formulation and assessment meet, and indeed may overlap. Therapists assess to find out about problems and their context, and they formulate differently according to what they think their findings mean.

Patients' comments may need clarifying during assessment if they are to inform the process of formulation maximally. Statements that are apparently clear to the person expressing them may not be clear to the therapist, or may reveal ambiguities and contradictions, as when angrily saying "I'm not capable as a parent" (when sadness sounds more likely and, superficially, more appropriate), or when commenting wryly that "I felt sorry for myself," without elaborating on what that means. One of the most useful sources of information for formulation comes from the mutual reactions of the patient and therapist to each other—information that is used differently in different types of therapy, and which is understood using different theoretical systems, of varying degrees of sophistication, but which is always relevant.

The processes of assessment and formulation therefore go hand in hand, and inform each other, but they remain different processes. Ideas about how to understand (conceptualize or formulate) what is being said, about its personal meaning and implications for theorized psychological structures and processes, guide questions and observations. When formulating as well as when assessing, the information gathered changes and shapes these ideas as hypotheses are formed, revised, and (theoretically) refined. So, making a formulation is not a one-off activity that defines a fixed state, but the reflection of a dynamic process, and the resulting system of understanding develops and changes over time. This is why the process of formulation should start at the same time as the process of assessment—just as the process of finding ones way around a new place starts with the first encounter with it—and may be on paper rather than in person.

Two points that follow from this line of argument help to determine how a formulation is made. First, if therapists are always formulating as well as assessing, then their questions and statements should be guided by conceptual hypotheses. They should always be able to answer the question "Why did you ask that then?" The answer should not just be phrased in terms of curiosity or information gathering, but should relate to a hypothesis about how to understand the minutiae of the case. The patient's response to the therapist's comment or question is then maximally informative. This may sound unrealistically demanding, as if every sentence the therapist utters should be shaped by the developing formulation—indeed, it is intended as a rule of thumb rather than as a categorical imperative. However, it is less unrealistic than it might seem. The initial question in the therapist's mind could be quite a simple one, for example: Is the withdrawal described by this person associated with feelings of depression and sadness or is it a kind of avoidance motivated by fear? Will attentive listening help this person feel sufficiently comfortable to disclose significant material? Are my questions too specific and intrusive at this stage? Answers to these questions could of course lead to more complex ones: Is this person's reticence a product of experiences that have destroyed trust? Does it reflect a preference for an autonomous style of relating to others? Is it a product of inexperience and lack of practice or opportunity in talking about intimate and personal matters? Is this way of interacting culturally unfamiliar to them?

The second point is that the process of therapy should not be artificially separated into discrete stages of assessment, formulation, and treatment (or intervention). It is not that these processes cannot be distinguished, or that one or other of them may not predominate at a particular time, but that they cannot in practice be wholly separated from each other. Thus, one of the hardest tasks therapists have to learn is how to bear all three of them in mind at once—how to gather information, think about it in theoretical/structural terms, and remain aware of the various ways in which they are likely to exert an influence, so as to enhance the potential for productive change, rather than limit or delay it.

The many sources of information available to therapists when starting to develop a formulation, assuming an adequate process of assessment has been set in motion, are summarized in Table 2. This list includes both direct and indirect sources of information, information from standardized questionnaires, and from initial interventions such as self-monitoring and homework assignments (when these are used). The purpose of this summary, in the context of the preceding discussion, is not to overwhelm therapists with long and exhaustive lists of material to be gathered, items to consider, processes to complete, and so on, but to illustrate that there is an enormously rich source of relevant material potentially available, and the process of formulation can draw on any of it, beginning anywhere. The process of formulation is essentially one of abstraction and it works by relating observable phenomena to hypothetical underlying processes and mechanisms. It is not necessary to observe everything before making a guess at what lies underneath. An (informed) guess may either indicate the need for more assessment or it can short circuit the process. Because formulating is a dynamic process, and depends on the ability of the therapist to retain an open mind, the process can productively start to serve the functions listed in the previous section straight away. Therapists can focus their minds on the process of formulation by asking more formal questions: How can I understand the information I have been given in terms that make theoretical sense? What implications does that understanding have for what to do next? What difficulties will I have, working with this person? What difficulties will they have (working in this way) with me? What use will this person be able to make of treatment? Answers help to determine how to intervene and to predict what will or will not happen as a consequence.

6.01.4.2 Putting the Information Together

Given that a formulation provides connecting links between theory and practice, the precise form that it takes will be partly determined by the theoretical approach of the person making it. Nevertheless, some general points apply, and these are illustrated here using the cognitive-behavioral approach.

First, initial formulations can provide cross-sectional understanding of an aspect of the presenting problem. The most obvious example is probably that of a vicious cycle which summarizes the way in which a particular, readily accessible, symptom pattern is thought to be maintained. It is used here to illustrate the way in which a formulation helps to specify processes, links, and mechanisms. In this case the focus is on certain kinds of links. Other cross-sectional formulations might focus on other patterns, for instance in interpersonal functioning, sequences of behaviors and their consequences; thoughts, feelings, attitudes, and beliefs; dilemmas and traps. In this example (Figure 2), a woman living through a stressful period described feeling tired much of the time and being unable to relax. Asked about what goes through her mind when trying to switch off, she described a stream of worries, most of which were rather vague and hard to specify in detail. The worry disturbed her sleep pattern, which exacerbated the tiredness. A cycle, which symbolizes how one thing leads to another, can easily be illustrated diagrammatically, and it has obvious implications. Breaking the links will help to solve the problem, and this can be done in various ways, such as learning to relax, identifying and dealing with the worries, or taking hypnotic medication. The assumption behind the formulation so far is that the problem will subside if the process that maintains it is interrupted, and the intervention selected could be determined by the preferences, understanding, or skill of either of the parties involved.

However, a formulation essentially relates theory to practice. Applying the cognitive model to this case would suggest that a close relationship between thoughts and feelings is likely to be of central importance. There are at least three ways in which this initial formulation, in its hypothetical and simplified form, can help the cognitive therapist to focus on factors that theoretically are likely to be relevant. It identifies worry as an important cognitive-maintaining factor, it reflects an overall understanding of the problem, suggesting that the symptom pattern is recognizable, understandable, and changeable—attitudes which may differ strikingly from those the patient starts with—and it poses questions about the context of the problem. Nothing has been specified

Table 2 The main sources of information for use in formulation.

Examples of direct information

- Reports of present phenomena: cognitive, affective, behavioral, and physiological
- The context: historical background and development, real life problems
- Reactions, comments, and expectations, about the self, others, therapy, events, etc.
- Interactions within therapy: ability to relate, tenor of relationships
- Observations of body position, movement, facial expression, eye contact, etc.
- The outcome of interventions such as self-monitoring, homework assignments, behavioral experiments, etc.
- Products of questionnaires, tests, standardized interviews, systematic observation, etc.

Examples of indirect information

- Knowledge about diagnosis: *DSM*
- Referral information: summaries, previous treatment, opinions
- Knowledge of cultural norms (of the therapist and of the patient)
- The socioeconomic and political context

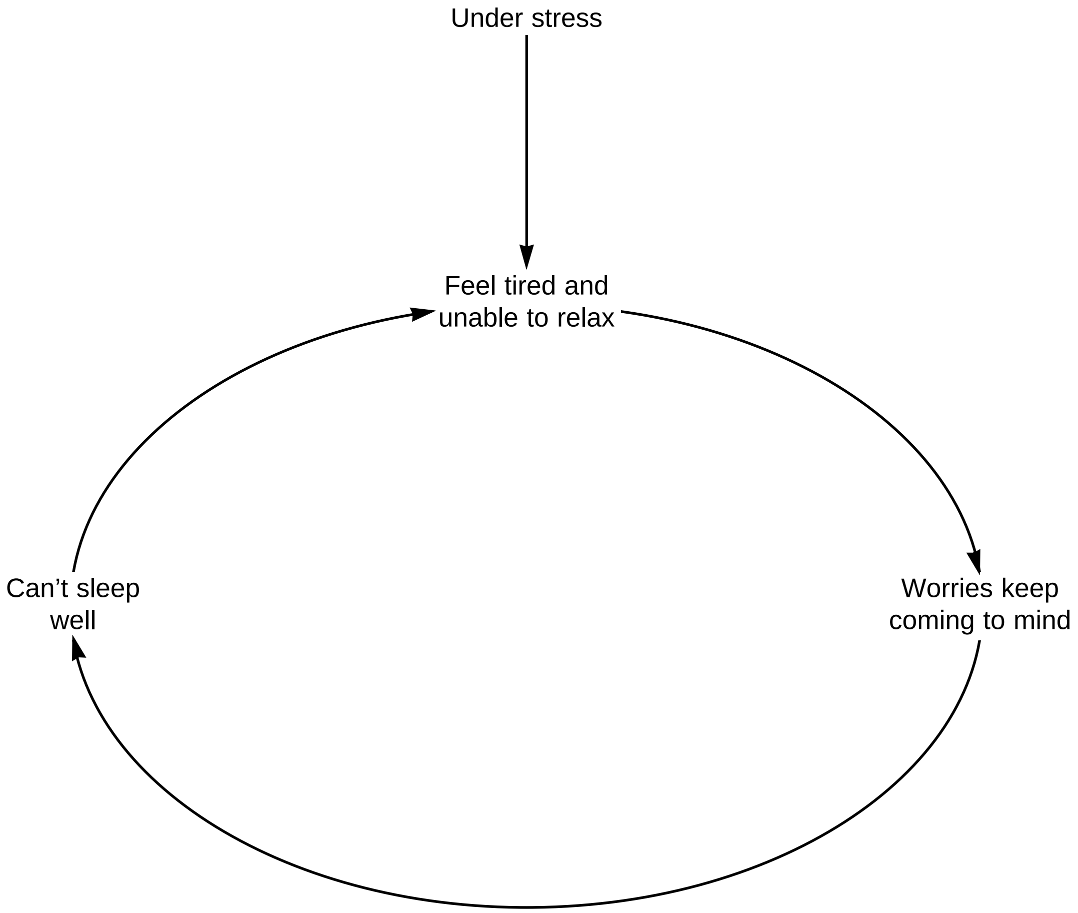

Figure 2 Example of a simple cross-sectional formulation: basis for a more complex formulation.

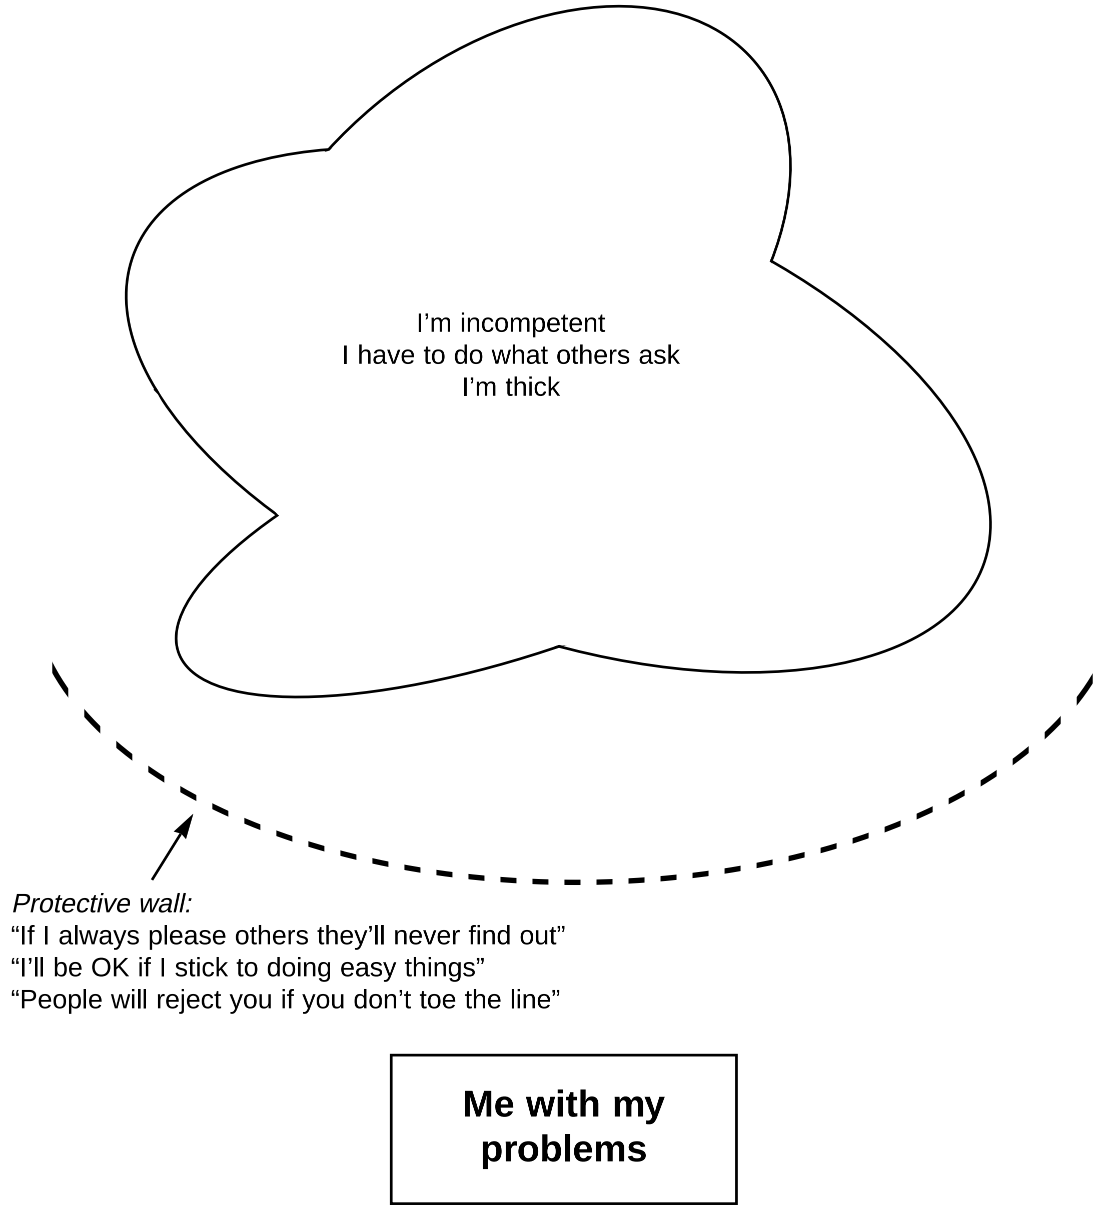
about why this is, for this person, a stressful period. Theory-driven questions help to develop more hypotheses: What does it mean about her habitual response to stress? How does she construe her present situation? What does her reaction to it mean to her—about herself, about other people, and/or about the world in which she finds herself? So, the initial formulation triggers further inquiry, and starting from a simple cross-sectional map can lead to more sophisticated levels of understanding, and to more complex formulations, as well as being practically useful. The precise way in which this happens will be determined by the theory being used.

Cross-sectional formulations can also provide an outline summary of the way in which complex underlying factors are understood, or of the way in which aspects of a problem are linked. Three statements made by an unemployed, unconfident young man with a wide range of social, interpersonal, and affective problems were used as the starting point for the initial formulation illustrated in Figure 3: "If I always please others they'll never find out about me," "I'll be OK if I stick to doing easy things," and "People will reject you if you don't toe the line." In this diagram, three aspects of his problem are represented in different ways. First there is a rather shapeless "thought bubble" at the top in which hypotheses about underlying cognitive structures, beliefs, attitudes, and rules about himself have been put into words: "I'm incompetent"; "I have to do what others ask"; "I'm thick (stupid) ... " These actual words were his responses to specific (theory-driven) questions, and they illustrate how the process of formulation interacts with that of assessment, and depends on the ability to abstract and to generalize. The broken line is labeled a "protective wall" because it represents the idea that the three statements listed—starting points for a more detailed formulation—reflect behaviors that serve a function. Reacting in these ways protects him from having to confront (the hypothetical) underlying beliefs and attitudes, and prevents others from discovering them, both of which would be painful experiences for him. However, these protective reactions cause problems, not specified here but referred to in the box in Figure 3. This formulation contributed to the process of developing a shared understanding of some complex problems, and it was used to explain how change would probably involve working at all three levels. It also has implications for decisions about general aspects of therapy. For example, it suggests that at times this will be a distressing process that will demand sensitivity and a good sense of timing from the therapist.

Cross-sectional formulations potentially reflect ideas about psychological processes and mechanisms as well as about the relevance and relative importance of different facets of a problem. Longitudinal formulations reflect assumptions about etiology as well. They are used in most kinds of therapy, and are readily illustrated in the case of CBT. The basis for using this theoretical model in clinical practice has been summarized in the form of a template (Table 3) which can be used to illustrate how theoretical understanding can be translated into practice. This shows that, theoretically, experience, both early in life and subsequently, gives rise to a set of beliefs and assumptions about the world, about other people, and about the self.



I'm incompetent
I have to do what others ask
I'm thick
Protective wall:
"If I always please others they'll never find out"
"I'll be OK if I stick to doing easy things"
"People will reject you if you don't toe the line"
Me with my problems

Figure 3 Example of a cross-sectional formulation.

These beliefs are seen as a product of the ways in which earlier events have been perceived, understood, and remembered. They can be functional or dysfunctional, actively influential or latent at any particular time, and relatively easy or hard to identify and to recognize. A critical incident (see also below) is an event that fits with a belief—being rejected for someone who believes they are not socially acceptable, or being let down for someone who believes that other people are unreliable or untrustworthy. Critical incidents activate the relevant beliefs and assumptions, and thus produce negative automatic thoughts (NATs). Then a variety of interacting cognitive, affective, behavioral, and physiological reactions follows. At this level the problem is theoretically maintained by cyclical processes of the kind summarized in the cross-sectional vicious cycle described above.

Clearly a template such as this can be used to structure information about a patient, and this will have implications for what the therapist does. For instance, if it appears that dysfunctional beliefs play a small part in the presenting problem, or are well balanced by a set of positive beliefs, the theory (and the formulation derived from it) suggest that the work should focus predominantly on the level of maintaining factors. Another type of implication might reflect the degree of verification available for the theory. For example, psychologists do not yet know which are the most effective ways of changing beliefs (the cognitive frameworks with which people approach the world). One common strategy is therefore to begin working at the level of the NATs and to evaluate the degree of belief change that follows. The processes of change may, or may not, be set in motion by work at this level. If not, then another hypothesis might be that one of the many processes now available for changing beliefs should be adopted as well as or instead of. This example is not meant to explain how to do CBT, but to illustrate how the internal map provided by a theoretical understanding relates to a specific formulation, and how therapists can use such maps as guides even when there is incomplete evidence for the theories upon which they are based. Doing so enables them to explain what they have been doing, and it enables others to decide whether their actions were skilful, appropriate, and so on.

6.01.4.3 Key Factors and Basic Elements

This example also illustrates that when learning how to construct a formulation, it can be helpful to think in terms of key factors. Critical incidents provide a good example of these as they reflect the way in which hypothetical underlying mechanisms are manifested, and link these with observations about present phenomena. Critical incidents are "critical" because they provoke a high degree of affect, often in excess of what might otherwise be expected (an over-reaction, such as becoming enraged if kept waiting for 10 minutes); they are easy to notice and remember, and are of special significance for the person who experiences them. Examining them potentially reveals other elements of the CBT template: underlying

Table 3 Template for a longitudinal formulation using cognitive-behavior therapy.

Experience (early or otherwise)

↓

Beliefs, about the self, the world, and others, which are expressed in categorical statements: I am . . . ; the world is . . . ; others are . . .

↓

Assumptions derived from beliefs, which can be expressed in conditional statements: If I . . . then . . . ; One should . . . otherwise . . .

↓

Critical incidents

↓

Activated beliefs and assumptions

↓

Negative automatic thoughts (NATs)

↓ ↑

Cognitive, behavioral, affective, and physiological reactions beliefs, preferred coping mechanisms, maintenance cycles, and so on. Focusing on critical incidents is thus theoretically helpful when stuck in constructing a cognitive formulation. This is not to say that all cognitive therapists think about them, or base their formulations upon them. An alternative method might involve working from a problem list, weighting the problems for importance, and going on to abstract and understand the connecting themes and links in ways that fit with the theory. The point is that within a particular method of working there are many ways of constructing a formulation, but it can be helpful to keep those factors in mind which play a central part in the theory, or in revealing the manifestations of important theoretical constructs whether these are core beliefs, core interpersonal schemata, or core conflicts. To repeat, there is no single correct method.

Use of the word "core" suggests that formulations may be thought to have certain basic elements, and that unless these are identified the formulation will, in Perry et al.'s words, "lack an integrative coherence." When writing about psychodynamic formulation and about central conflicts, Perry et al. (1987, p. 546) say "The aim is to find a small number of pervasive issues that run through the course of the patient's illness and can be traced back through his or her personal history, and then to explain how the patient's attempts to resolve these central conflicts have been both maladaptive ... and adaptive." The overall intention is clearly closely similar across different therapeutic orientations, as is the general approach: first, apply a particular, theory-driven model; if that does not in practice fit the particular case, explore further using questions and trial and error in the (scientific) search for a formulation that fits better.

This process might be facilitated if there was agreement over which were the basic elements of a formulation and an atheoretical way of linking them together. One way of doing this has been developed by Goldfried and his collaborators. This transtheoretical coding system "was developed as a common language for use in conducting comparative process research across orientations" (Goldfried, 1995, p. 222). It specifies which are the relevant components of functioning (e.g., self-observation, self-evaluation, intention, emotion, and action) and the types of links that can be made between them (vicious cycles, patterns, contradictions). These can be manifested both in intra- and interpersonal contexts, involving other people or not, over a particular time frame. One advantage of this type of formulation, the coding system of therapeutic focus (CSTF), is that it indicates what the problem is, and where to intervene, but (being atheoretical) cannot indicate how to do so. It cannot therefore provide specific implications for treatment, but it does provide a common language, and using this it is potentially easier to find out precisely how theories differ when put into practice.

6.01.4.4 Issue of Completeness

The formulations illustrated so far have been kept simple for the sake of clarity, to emphasize the point made at the beginning about the principle of parsimony, and because they demonstrate the point that it is never too soon to start formulating. They are examples of initial hypotheses. As treatment progresses they would be likely to become more complex and also to take more account of a person's developmental history and the supposed underlying mechanisms.

This raises an important issue for discussion. Many people assume that formulating is a difficult and lengthy process, the aim of which is to encompass, systematize, and explain all relevant factors about a particular case. This view can lead therapists either to bypass the process of formulation and start treatment straight away, or to delay the start of treatment until they have got the picture right. Both of these reactions cause problems: bypassing the process makes it hard to move beyond the stage of trial and error; interventions are selected in the absence of a coherent underlying strategy. This seems to be successful when the patient responds well (as many patients do initially), but it leaves both parties feeling confused and unable to understand what has happened when half a dozen sessions later progress is halted and setbacks are encountered. It is rather like trying to stop a car rattling by cleaning and adjusting those parts of the engine that are most accessible. Delaying the start of treatment is another false economy, for many reasons: the initial momentum provided by a fresh start and a new encounter may be lost; the impact of being listened to, heard, and understood by someone new may be dissipated; and the goodwill, advice, and new ideas derived from interacting with a trained therapist may not be harnessed in a way that is either helpful or informative (or both). So, opportunities to test hypotheses may be lost.

In an ideal world therapists, believing that "at some level it all makes sense", would be able to use their formulations to make sense of the material presented in a particular case. But at present complete formulations, like complete theories, are not possible. A person cannot be summarized in a diagram. But some of their problems and patterns of behaving can be understood in theoretical terms and this understanding can be represented in a way that helps to guide treatment. The complexity and accuracy with which this is done varies according to the stage of treatment.

The emphasis on completeness that is often found in discussions about conceptualization may be a consequence of the historical associations between medical practice, psychiatry, and psychology, and the common use of the word "treatment" to refer to the actions of people trained in those professions when they are trying to help others. The assumption is that it could be dangerous to miss something serious or to apply the wrong treatment. So, a complete understanding is supposedly an essential (or important) prerequisite for deciding how to intervene.

The situation is different in psychotherapy (or psychological therapy), first because the psychological influence of one person on another cannot be withheld (as can a medical treatment), and then applied when ready, in a self-contained package. Various (partially unspecified) factors are always operating, and in psychotherapy the ways in which these function will to some degree be influenced by the theoretical views and assumptions of the therapist (as well as by their personal characteristics). The business of formulating can direct this process, clarify what is intended, and make the way in which theories are being applied accessible. Formulations do not have to be complete to perform this function but the method of working with them does have to be in place. Second, when dealing with psychological matters, the process of formulation is overtly interactive. Patients' comments and reactions contribute to the process; their opinions are relevant, and these may change over the course of treatment.

6.01.4.5 Conceptualizing Processes of Change

Therapists seek understanding of the way in which change takes place as well as of the way in which problems arise and persist, and they may also formulate this understanding in theoretical terms. Conceptualizing the processes of change is thus another way of relating theory to practice, and formulations may be technical, phrased in terms that are derived from the particular theory being used, or metaphorical. Technical formulations might explain how changing reinforcement patterns would change behaviors, how change in one person will prompt the system around them to adjust, or how changing patterns of defensiveness might change opinions of the self. Examples of metaphorical formulations are provided in this section to illustrate how metaphors can encapsulate information about complex processes that may be hard to specify otherwise. Some examples are well known and their use has become quite conventional, such as "a journey of a thousand miles begins with the first step." Others are created in a particular therapy context. For example, a manager of an engineering company, whose habitual rigidity was exacerbated by various (personal and industrial) crises, saw himself as "hanging on for dear life," and being unable to contemplate change. He was asked to think about how to build a building to withstand an earthquake. Thinking about this enabled him to reconceptualize change as a way of developing the combination of flexibility and rigidity needed to provide stability in difficult times. Another relatively simple way of representing and summarizing a complex process of change was spontaneously developed by a woman with longstanding problems involving low self-esteem and lack of confidence. She saw herself as "wobbly" and at risk of falling, as if trying to sit on a two-legged stool. The process of change for her was like "putting down the third leg." In practice this meant many things that contributed to a sense of stability: developing new skills and abilities, thinking about herself in new ways, and making more respectful and open relationships with those around her.

People often use metaphorical language to communicate their experience of distress. Indeed, it might be more accurate to say that it is difficult to describe such experiences without using metaphor—people explain to clinicians how they feel broken, trapped, fenced in, cast adrift, close to the edge, messed up, out of reach, cut off, high, low, and so on. Perhaps the most common methaphors describe life as a journey and ourselves as traveling through different kinds of emotional weather. Patients' understanding (or personal formulation) of the processes involved is also reflected in the words used to describe their experiences: "I've hidden myself away ... built a protective wall around me ... had to harden my shell ... can't see my way out of the tunnel ... waited to be rescued." It is hardly surprising that the processes involved in therapy are similarly described. Someone who came to understand the stultifying and self-destructive effects of overt compliance with the wishes of those around her, despite her own inclinations, and the relationship of this pattern of behavior to the fear and anger for which she was requesting help, said that she felt as if she had spent her whole life trying to grow flowers in her garden and cutting off the buds before they could flower. She saw therapy as a process that would help her to allow the flowers in her garden to bloom. Undoubtedly, the process of developing a shared understanding is a complex one, and the more abstract the material considered, the more difficult this process will be. Although a metaphor is not a formulation, and it may reflect only part of what is involved, using one can help to fulfill some of the purposes of formulation that were described above, and it can do so with a startling degree of economy and emotional sensitivity because it operates at more than one level.

These examples have been chosen because they illustrate a point not so far emphasized about formulation, that it is a way of summarizing meanings, and of negotiating for shared ways of understanding them and communicating about them. When these are complex it can be helpful to use metaphor, and of course this applies generally, not just when formulating processes of change. A formulation provides a source of common language, and when this is available it can then be used to relate a theoretical framework, at a high level of abstraction, to practice, so as to facilitate the process of change.

6.01.5 ACCURACY: HOW TO TELL IF A FORMULATION IS RIGHT

Formulations can never be shown to be right as they are hypotheses not statements of facts. The evidence may support them or it may not, and they should be judged according to probabilities rather than on an absolute scale of rightness. Like other scientific hypotheses, formulations can only be shown, conclusively, to be wrong. Nevertheless, practical guidelines are useful, and a number of attempts have recently been made to evaluate their inter-rater reliability and predictive validity (Barber & Crits-Christoph, 1993; Horowitz & Eells, 1993; Persons, Mooney, & Padesky, 1995).

6.01.5.1 Criteria of Accuracy

A summary of the kinds of practical guidelines that might provide clinicians with criteria of accuracy is given in Table 4. Unfortunately, the fact that a formulation makes good internal sense (provides a plausible narrative for instance) is not a guarantee of its accuracy, which should therefore be tested out in practice. It goes without saying perhaps that a formulation which is simple, clear, and easy to understand, and therefore easy to explain, is more readily testable than one which is overly complex. One which is more specific and low level will have clearer implications than one which is phrased in more general, abstract, and high-level terms. Presenting the formulation to someone else, or putting it onto paper, is therefore a useful and revealing exercise.

6.01.5.2 Questions for Research

It would probably be fair to say that, of the many questions that could be asked, few have been studied and none have been conclusively answered. Persons, Padesky, and Mooney (1996) found only moderately good inter-rater reliability of cognitive-behavioral formulations when tapes of initial therapy sessions were rated by a large group of therapists who had been trained in CBT, and who varied in their level of experience. Surprisingly perhaps, agreement was better with respect to underlying mechanisms than in listing patients' overt problems. Barber and Crits-Christoph (1993) found, when reviewing the psychodynamic literature, that when clinicians based their formulations on preset categories, formulations were more reliable, and in addition the predictions of the psychotherapy process and outcome were better. Both these findings fit with the view that the more clearly specified the activity (as in CBT and interpersonal psychotherapy, or when using clearly defined conceptual categories), the less room there is for wide-ranging, speculative inferences, and the more agreement there is both about particular case formulations and about their utility.

As discussed above, there has been some suggestion that making overall decisions about treatment purely on the basis of a diagnosis may be at least as useful as basing them on an idiographic formulation. However, a diagnosis only enables therapists to make general decisions about which set of interventions to employ; for example, to use exposure *in vivo* to help someone with a simple phobia, or those techniques that will assist in resolving a role dispute in a case of depression treated with interpersonal psychotherapy. In both cases the actual steps used will still depend on the way in which the individual case is formulated (Markowitz & Swartz, 1997). The question as to whether treatment that is based on a formulation is more successful than treatment that is not is more complex than at first appears. Most clinicians bring their theoretical knowledge to bear in the way that they understand, and communicate understanding about, a case. They use covert formulations, which may not be made overtly communicable even though they inform and direct the process of treatment. This happens because, once therapists are

Table 4 Ten tests of a formulation.

1. Does it make theoretical sense?
2. Does it fit with the evidence? (symptoms, problems, reactions to experiences)
3. Does it account for predisposing, precipitating, and perpetuating factors? (both overall and with respect to episodes of difficulty)
4. Do others think it fits? (the patient, supervisors, colleagues)
5. Can it be used to make predictions? (about difficulties, aspects of the therapeutic relationship, etc.)
6. Can you work out how to test these predictions? (to select interventions, to anticipate responses and reactions to therapy)
7. Does the past history fit (with respect to the person's strengths as well as weaknesses)
8. Does treatment based on the formulation progress as would be expected, theoretically?
9. Can it be used to identify future sources of risk or difficulties for this person?
10. Are there important factors that are left unexplained?

thoroughly familiar with the theoretical background to their work, and with the process of map-making, the activity of formulation cannot be wholly suspended. Once able to recognize signs of core beliefs or core conflicts, for example, such theoretically meaningful constructs cannot suddenly be rendered invisible again. Formulation skills may still need sharpening, and there is certainly a need for more and better training (Sperry, Gudeman, Blackwell, & Faulkner, 1992), especially now that clinicians appear increasingly likely to incorporate ideas from theoretical orientations other than their main one into their work (Messer, 1996b). The effects of working with (or without) a formulation will remain hard to evaluate. The more important question, in practical terms, is whether or not a particular way of seeing things is put to good use, successfully to do the things that a formulation is for. The struggle is to find a way of seeing things that helps. Although the assumption that "at some level it all makes sense" still underpins much clinical work, it is not necessary to believe that there is such a thing as a "correct" formulation. As Messer (1996a, p. 136) says, "An alternative outlook is that there is no one version of truth possible because we largely construct our realities, which inevitably leads to multiple perspectives on that reality. Wearing different glasses provides different views of the world."

6.01.6 USING THE FORMULATION: PRACTICAL ISSUES

A formulation does not have to be correct, but it does have to be useful. The purposes of formulation are discussed in Section 6.01.3. Here, three practical factors that influence whether a particular formulation succeeds in fulfilling its purposes are mentioned briefly.

6.01.6.1 The Value of Organizing and Clarifying

Formulating is a way of classifying information, putting it into (conceptual) boxes, and drawing links between them. It organizes information, treatment strategies, and the choice of interventions, and it also clarifies understanding of a case, and therefore the meaning of what is observed. This process has some less obvious advantages as well as the obvious ones. In particular, it helps therapists to see problems and difficulties as understandable, and this influences their attitudes and expectations. For example, hostile or passive–aggressive behaviors frequently create frustrations and difficulties for therapists, especially when they persist despite all their best efforts. Organizing and formulating the information helps therapists to see these as characteristic and predictable difficulties for which they can plan appropriate strategies.

6.01.6.2 Developing an Internal Supervisor

The process of formulation provides therapists with an opportunity to achieve on their own many things that otherwise they would achieve through supervision. It prompts them to reflect about their work with individual cases, and to rethink when progress seems blocked. It helps them to become aware of their own assumptions and beliefs, and to look out for ways in which these may cause problems, such as making it hard for them to notice, understand, or work with particular issues. It helps them to work well with unusual cases or with types of problems that they have not previously encountered. In doing so it helps to build confidence. Formulation is no substitute for supervision but, used well, it complements and extends it—provided that the formulation does not become a fixed way of seeing things that obscures the significance of information that does not fit.

6.01.6.3 Communicating a Formulation

Some obvious principles can be derived from the preceding arguments: the simpler the formulation, the easier it will be to communicate; it should be presented as a hypothesis, not as fact; and initial guesses are worth checking out as they can indicate whether a particular way of seeing things is likely to be productive.

To some degree a formulation is a matter of judgment. It is based on clinical judgment as well as on knowledge and facts. As judgments about people are bound to reflect some of the attitudes and assumptions of the person who makes them, the question arises as to what should be done with those judgments. Who should be told about them? Are there people who should not be told, or circumstances in which they should not be disclosed?

Answers to these questions are partly determined by practitioners' ethical guidelines and procedures for professional accountability. They also depend partly on the theoretical orientation of the therapist. In cognitive analytic therapy, interpersonal psychotherapy, CBT, and in some forms of short-term psychodynamic psychotherapy, therapists make their formulations explicit, and have therefore considered carefully how and when this should be done (Beck, 1995; Beck, Freeman, & associates, 1990; Butler & Booth, 1991; Markowitz & Swartz, 1997; Ryle, 1995). The method used is immensely variable, using imagery, metaphor, diagram, or verbal explanation, presented in person or in a letter. There is room here for creative thinking, and sensitive adaptation of communication skills, though it may help to specify some general principles.

Being on the receiving end of a formulation can feel like being weighed up, evaluated, or judged—like being "seen through" or "rumbled" rather than understood. This is less likely if the formulation is presented questioningly and collaboratively, at a time when therapists are clear that patients are able honestly to give feedback, and while thinking about how to facilitate the process of feeding back reactions in a way that is not just superficial or polite. It is important to focus on strengths as well as weaknesses, and to draw out implications for change, otherwise patients with chronic problems may conclude that "this is the way that they are," and become hopeless about change. The language used should be simple and jargon free. It may help to give a small amount of information at a time and to be ready to repeat explanations, or introduce technical terms, as necessary. Therapists often underestimate how much patients can themselves contribute to the process of formulation, for instance, by elaborating details, filling in missing links, or providing contradictory information that shows how the formulation can usefully be adjusted.

Formulation thus goes hand-in-hand with reformulation, and it is this, as Rosenbaum (1996) points out, that stops it becoming a way of "fitting something to a known formula."

6.01.7 CONCLUDING DISCUSSION

Formulations reflect the way in which therapists make sense of someone else's predicament. They reflect the assumptions brought to bear when thinking about it, the theories learned, and the meaning made of it. However, making sense is not the only thing that they do. All therapists are aware that sometimes (albeit rarely) providing a formulation can be sufficient to bring about change. Such cases show that formulations do more than supply understanding—they enable someone to see things differently, to reformulate, or to find a new meaning. A business executive whose whole career was threatened by an episode of severe stress and anxiety was suddenly able to see himself as engaged in a genuine struggle. It was then legitimate, in his view, to experience reactions indicative of both fight and flight. His symptoms became acceptable, diminished immediately, and he remained well over the following six months. Of course this could be understood in many ways: as a healthy consequence of a reformulation, as a miracle cure, or as a flight into health. So therapists are also in a predicament. Most of the time only some of the facts are available to them, whether these are about someone's past life, their internal experience or their present relationships, and the facts that are available are consistent with a wide range of plausible interpretations. Different mechanisms can be inferred from the same event, as in the example above, or from the same overt problems—the bather's hand movements could signify waving or drowning. Equally, the same mechanisms could be inferred from different problems—a fear of abandonment could underlie both hostile and dependent behavior. The skills of functional analysis may help to advance the process of formulation here. To end where we began, Frank (1986, p. 343) said that "the best hope of bringing conceptual order into the field of psychotherapy may lie in thinking of all psychotherapeutic enterprises as lying in the realm of meanings" ... thinking, feeling, and behavior are ... "responses to the meanings of events as much as to the events themselves." Our assumptions and knowledge about the ways in which these meanings are stored, represented, and recalled, and about the degree to which they can be brought into awareness, will therefore greatly influence the meaning we give to our formulations and the uses we make of them.

Therapy can be understood in many ways—as managing anticipated transferences, countertransferences, and resistances; as seeking new perspectives and using these to restructure a belief system; as a process of constantly meeting and adjusting to what is happening each moment; or as a way of influencing the contingencies that relate behaviors to their antecedents and consequences. In all of them, the process of formulation serves similar functions. It is useful because it helps to determine what we, as therapists, do and enables us to understand and to explain that better.

6.02.1 INTRODUCTION

More than most other psychotherapeutic approaches, behavior therapy has been the subject of misunderstandings. While the self-image of behavior therapists and research results consistently yield the positive image of a pragmatic, problem-solving, empathic, and frequently successful approach, the outside perception is often quite negative. The scientifically oriented language of behavioral publications seems to have led some observers to the conclusion that behavior therapy is a highly technical endeavor that neglects human relationship factors. Indeed, surveys of the acceptance of behavior therapy (Eschenröder, 1994; Heekerenz, 1991; Lutz, Bezold, Bloem, Dietrich, & Wittmann, 1992; Woolfolk, Woolfolk, & Wilson, 1977) frequently show negative judgments which often are more pronounced in persons that have little information on the approach. A remarkable example on attitudes toward behavioral approaches is given below.

"A rose by any other name . . . : Labeling bias and attitudes toward behavior modification" Using this title, Woolfolk et al. (1977) published two studies, in which beginning and advanced students in educational sciences had been shown a film excerpt of a teacher who applied reinforcement methods. Half of the subjects had been told that the film would show the application of "humanistic methods." For the other half, the method was labeled "behavior modification." This simple labeling massively influenced the ratings of the teacher and the session. With the "humanistic" label, subjects in both studies rated the teacher significantly more positive, competent, flexible, and personally attractive. Moreover, they expected clearly better academic results and emotional growth from the "humanistic" method. The authors attribute their results to the negative effects of a frequently technical and mechanistic presentation of behavioral methods.

In addition to external misunderstandings, there are also "self-misunderstandings" and discrepancies that result from the broad and frequently stormy development of the behavioral approach. Today, there are many different types and opinions about behavior therapy. For example, the classical approach of Joseph Wolpe is as different from modern cognitive-behavior therapy as is traditional progressive muscle relaxation from Öst's applied relaxation or the early operant treatment of depression from Beck's cognitive-behavioral approach. The reasons for the misunderstandings on behavior therapy have been sought in the polarizing form of its early self-presentation, in a lack of information of the public, in feelings of threat in the face of superior proofs of efficacy, in hostility toward rational science, etc. But regardless of their origins, the misunderstandings clearly show how important an explicit discussion of the nature of behavior therapy is.

In the "founding phase" there was a relative consensus on the definition of the term "behavior therapy." It was generally agreed that this was the clinical application of the learning principles that had been established by psychological research (cf. Eysenck, 1959). However, behavior therapy was even in its beginnings a heterogeneous movement of considerable broadness. Feedback from growing clinical practice and vivid research quickly softened the classical learning theory understanding of behavior therapy. Together with the progress in the underlying psychological science, its claim to be theoretically founded and empirically tested generated an ongoing discussion. It is therefore hardly surprising that a large number of definitions has been proposed.

6.02.1.1 One Behavior Therapy or Many Behavior Therapies?

Definitions of behavior therapy typically have varied with respect to the broadness of theoretical orientation and underlying methodology. Wolpe (1976) saw behavior therapy solely as methods that have been derived from experimentally established principles and paradigms of learning. Similarly, Eysenck (1959) understood behavior therapy as an attempt to change human behaviors and emotions based upon the laws of modern learning theory. According to Agras, Kazdin, and Wilson (1979), behavior therapy included already in the 1970s behavioral and cognitive approaches. Even broader, Hollandsworth (1986) saw behavior therapy generally as the application of scientific methods to clinical problems. In the same vein, Yates' (1970) influential definition emphasized that behavior therapy utilizes all the scientific knowledge accumulated in psychology and its neighboring disciplines. Among other important definitions were those by the Association for the Advancement of Behavior Therapy (see Franks & Wilson, 1975) and by Rachman (1988).

The considerable variability of these definitions makes it even more important to ask what constitutes modern behavior therapy. An "eternal" answer to this question is not possible. The mere attempt to answer this question "once and for all" would counterproductively institutionalize the status quo and impair future developments. The continuous evolution of behavior therapy implies that the question about its nature has to be discussed at more or less regular intervals. The next section is therefore devoted to a characterization of modern behavior therapy at the end of its first half century of existence. This is followed by a brief sketch of its historical development in order to better understand its present position. Section 6.02.4 is devoted to the important question of the empirical status of behavior therapy and the practical consequences that this should imply. The chapter ends with a discussion of some of the problems and criticisms of behavior therapy in today's practice and research.

6.02.2 WHAT IS MODERN BEHAVIOR THERAPY?

A mere definition is not sufficient to adequately describe the nature of behavior therapy (Margraf, 1996; Margraf & Lieb, 1994). Any meaningful characterization that is open to the future needs to discuss the basic principles, methodological position, and etiological approach that underly the behavioral approach. Moreover, the characterization could easily become a listing of abstract statements if it does not include typical treatment methods and their indications.

6.02.2.1 Definition

Behavior therapy is a genuine psychological treatment approach that includes a large variety of specific techniques and interventions. In clinical applications, these different methods are utilized either alone or in combination depending on the nature of the problem to be treated. Behavior therapy can therefore not be understood as a single, circumscribed treatment method that relies on one single theoretical model. On the contrary, its theoretical background is composed of a multitude of general and disorder-specific etiological theories and psychological models of change. The common link is the orientation toward empirical psychology. A future-oriented characterization cannot limit itself to a list of present methods. The definition of behavior therapy therefore has to fulfill the following requirements:

(i) the theoretical and methodological breadth of the behavioral approach needs to be included;

(ii) in spite of broad borders the specific aspects of behavior therapy have to be named explicitely; and

(iii) openess for future developments.

This has led me to the proposal to consider the behavioral approach as a broad basic orientation rather than as a single therapy school or group of treatment methods (Margraf, 1996; Margraf & Lieb, 1994). Modern behavior therapy can then be defined as follows: Behavior therapy is a broad psychotherapeutic orientation that is based upon empirical psychology. It includes disorder-specific and general treatment methods that aim at a systematic improvement of target problems on the basis of as much as possible tested knowledge of disorders and psychological principles of change. Interventions have concrete and operationalized goals on the different levels of behavior and experience. They are derived from the diagnosis of disorders and individual problem analysis and target the predisposing, triggering and maintaining conditions of the problem. Behavior therapy is continuously evolving and explicitly asserts to test its statements empirically. The levels of behavior and experience can be conceptualized in different ways. In behavior therapy, they are typically defined according to Lang's three-systems model (1971). This includes a behavioral, a subjective, and a physiological level of response. Although this model can be criticized in some respects (e.g., Fahrenberg, 1987), a multimodal approach has become the standard in most of behavior therapy research (Seidenstücker & Baumann, 1987).

6.02.2.2 Basic Principles

More important than the abstract definition is a concrete description of the basic principles that underly all of behavior therapy. These can be conceptualized as follows (Margraf, 1996).

6.02.2.2.1 Principle 1: behavior therapy is based upon empirical psychology

Empirical psychology is the scientific foundation of the behavioral approach. Behavior therapy therefore endeavors to operationalize its theoretical concepts and therapeutic methods and to test them empirically. Testing should be comprehensive using objective, reliable, and valid measurements. In addition to psychological knowledge on change principles and methods, the findings of nonpsychological neighbor disciplines such as biology or medicine are taken into account.

6.02.2.2.2 Principle 2: behavior is problem-oriented

Treatment as a rule aims at present problems. Therapeutic proceedings are as much as possible tailored to the respective disorders and individual patients. Thus, different disorders are typically treated in individualized form with different methods that are based upon empirical knowledge of the disorder. Beyond the solution of the actual problem treatment typically strives for a general increase in problem-solving capacities. This can be achieved indirectly by making the therapeutic interventions transparent or by promoting new experiences and directly by problem-solving trainings.

6.02.2.2.3 Principle 3: behavior therapy addresses predisposing, triggering, and maintaining problem conditions

Behavior therapy distinguishes between predisposing, triggering, and maintaining factors. Interventions target those conditions whose alterations are regarded as necessary for a durable solution of the problem. Often these are the maintaining conditions, because they are especially important for future well-being. With respect to predisposing and triggering conditions, most often their present effects are at the center of attention, because these types of problem conditions typically cannot be changed *post hoc*.

6.02.2.2.4 Principle 4: behavior therapy is goal-oriented

Identification of the problem and the joint definition of treatment goals are integrative parts of behavior therapy. The problem is the target of the treatment, its solution means that the goal of treatment is attained and the intervention can be terminated. Ideally, the explicit agreement on treatment goals should prevent the pursuit of different goals by therapist and patient or the subsistence of unrealistic expectations.

6.02.2.2.5 Principle 5: behavior therapy is action-oriented

The success of most behavioral treatments presupposes an active participation by the patient. Mere insight is not a sufficient condition for the alteration of fixed problems. Behavior therapy therefore does not limit itself to the discussion and reflexion of problems, but motivates the patient to actively try new behaviors, experiences, and problem-solving strategies.

6.02.2.2.6 Principle 6: behavior therapy is not limited to the therapeutic setting

Behavior therapy strives for a generalization of therapeutic effects on everyday life. The therapeutic setting and a good therapeutic relationship offer the framework for learning and testing new behaviors and experiences. They do not, however, ensure transfer into the patient's individual environment. For this, the patient has to practice newly acquired strategies between sessions. Although behavior therapists frequently accompany their patients for exercises outside of their office, the ultimate goal is always to master problems without therapeutic assistance.

6.02.2.2.7 Principle 7: behavior therapy is transparent

Behavior therapy wants its patients to be informed and active. A plausible model of the disorder, an explicit treatment rationale, and the intelligible explanation of all aspects of the therapeutic interventions are parts of behavior therapy that fulfill the legitimate need of the patients for an understanding of their condition. They elevate treatment acceptance and help to prevent relapse. Transparence thus increases compliance, comprehension of the treatment process, and indirectly problem-solving capacity. In this way, the acquired skills are better available for application to future problems without requiring renewed therapeutic assistance.

6.02.2.2.8 Principle 8: behavior therapy helps the patients to help themselves

Beyond the increase in general problem-solving capacity and the transparent derivation of therapeutic actions from an explanatory model of the disorder, the treatment aims at giving the patient skills for the independent analysis and mastery of future problems. Behavior therapy thus increases the patient's self-help potential and prevents relapses and the development of new problems.

6.02.2.2.9 Principle 9: behavior therapy strives for continuous development

Behavior therapy's orientation on empirical psychology leads to a permanent process of evaluation and further differentiation of its theoretical concepts and practical procedures. Behavior therapy therefore continuously evolves.

6.02.2.3 Hollywood or Realistic Expectations: Treatment Goals in Behavior Therapy

What claims should or may psychotherapy make? Some patients and therapists pursue a "hollywood perspective," in which the end of treatment should be like the happy end of a movie. After successful cure the patient disappears from the therapist's office into his life like the victorious cowboy from the movie screen. Although it has become an acknowledged triviality that for instance love stories end regularly when the relationships and thus new challenges begin, the image of permanent happiness shows an astonishing persistence in the "therapy market." Yet, far-reaching explicit or implicit promises of entire restructuring of personalities, complete freedom from problems, "imploding" symptoms, everlasting happiness, and perfectly painless mastery of life are not only unrealistic but also harmful. Disappointed hopes are especially embittering. Compared to the hollywood standard, one's own achievements and experiences may look like failures. They pursuit of chimeras wastes energy and diverts from realistic coping. The more one believes in "healing promises," the more dependent one gets. Psychotherapy cannot mean lifelong guidance. Realistic treatment goals therefore have to be coping and help to self-help. Even in complex problem constellations, therapy can at best attempt to teach new ways of coping and to identify cardinal points that can be used to break old habits. Psychotherapy can teach swimming, but the swimming has to be done by oneself.

6.02.2.4 Underlying Methodology

Behavior therapy sees itself as an applied science whose understanding of science is strongly influenced by methodological questions. Being that part of logics that deals with the logics of research and methods in general, methodology is a central constituent of the theory of science. It makes statements about questions such as "what is a hypothesis" or "what is the goal of scientific research." The methodology of behavior therapy is typically called "methodological behaviorism." This may not be confounded with other types of behaviorism.

6.02.2.4.1 Different types of behaviorism

The term behaviorism was from its early beginnings part of the struggle of paradigms in psychology. Coined by Watson in order to push his view of scientific psychology, the term was later used primarily by the opponents of Watson, Skinner, and their followers. The intense debate frequently overlooked that there is not a single type of behaviorism; instead there are several competing positions. The most common classification differentiates three types of behaviorism.

(i) *Methaphysical behaviorism* denies the existence of consciousness or mental events. The object of psychological science is exclusively seen in observable (overt) behavior (prominent advocate: Watson).

(ii) *Radical behaviorism* (also called analytical behaviorism) is a version of radical materialism which asserts that the world consists only of one matter. Mental phenomena are regarded as mere linguistic illusions that can therefore not be the object of scientific psychology (prominent advocate: Skinner).

(iii) Opposed to these two types is *methodological behaviorism* that defines itself not through statements about the existence of mental phenomena but through methodological guidelines that distinguish scientific from nonscientific procedures. Even though many representatives do not use the term, methodological behaviorism represents the majority in today's empirical psychology, including, for instance, cognitive psychology.

The basic guidelines of methodological behaviorism as it is applied today in clinical psychology and psychotherapy can be summarized as follows (Margraf, 1996; Reinecker, 1994; Westmeyer, 1984).

6.02.2.4.2 Guideline 1: the search for lawfulness

The goal of scientific work is to find lawful relationships that permit description and explanation of the subject of investigation. "Laws" do not have to be deterministic, probabilistic statements are also recognized. As a rule, different classes of causes are distinguished, although functional relationships traditionally have attracted most attention (see Section 6.02.2.5).

6.02.2.4.3 Guideline 2: observability

Only observable events or phenomena that are regularly related to observable signs can be subject of scientific analyses. This does not imply the restriction to observable motor behavior as the exclusive subject of psychology. Today behavior and experience are the widely recognized subjects of the discipline. Interestingly, even Skinner did not refuse introspection as a method if it fulfilled the above requirement.

6.02.2.4.4 Guideline 3: operationalization

Assessment of the subject of research has to be guided by explicit measurement instructions. Theoretical constructs have to be operationalized, that is, it must be stated in what way they are represented in variables that can be assessed empirically.

6.02.2.4.5 Guideline 4: empirical testability

Hypotheses principally have to be accessible to empirical testing, and they must be sensitive to experience. Immunizing strategies that attempt to make theoretical statements irrefutable are unacceptable because they prevent possible progress in scientific knowledge. Testing of hypotheses can operate through confirmation or refutation. Under the influence of Popper the possibility to falsify general hypotheses ("for all X is true ... ," e.g. "all mental disorders derive from learning") has gained great importance. Also relevant is the verification of hypotheses of existence ("There are some Y, for whom is true ... ," e.g., "some phobias are acquired by classical conditioning").

6.02.2.4.6 Guideline 5: experimentation

The best method to test statements is offered by controlled experiments (which do not necessarily have to be conducted in the laboratory). For ethical and pragmatic reasons, the experimental method has clear limits in clinical research. Often important variables cannot be varied arbitrarily as would be implied in a true experiment. Thus, it is ethically unacceptable to induce mental disorders for experimental reasons. At the most, weak experimental analogues for pathological states may be induced transitorily (e.g., hallucinations, sensorical deprivation, anxiety states, false feedback of performance). However, the question for the ethically acceptable limit has to be answered for each individual case. The opposite approach to reduce pathological states or to treat mental disorders also bears ethical problems when conducted in an experimental frame. For instance, randomization of patients to treatments presupposes informed consent. Therefore, research often has to rely on quasi-experimental designs.

6.02.2.5 The Etiological Approach of Behavior Therapy

The time of the "great" monistic theories to explain all mental disorders by one cause or constellation of causes is over. It has become obvious that such complex phenomena cannot be explained by simplistic or reductionistic "solutions." Today, slogans such as "biopsychosocial approach" or "vulnerability–stress model" dominate the debate. These, however, can be criticized for being overly unspecific or lacking concrete content. The behavioral approach attempts to identify specific causal constellations for individual disorders. Mental disorders are regarded as clinically significant behavioral or psychological syndromes or patterns that are accompanied by distress, disability, or reduced functioning on the behavioral, subjective, or social level.

It is important to distinguish between different classes of "causal" factors and to investigate their relevance to therapeutic change. The basic approach of behavior therapy differentiates between three major classes of etiological factors:

(i) *Predisposing factors:* These are also called vulnerability factors or diatheses. Pre-existing genetic, somatic, psychological, or social characteristics make the appearance of a disorder or problem possible or more probable.

(ii) *Triggering factors:* Psychological, somatic, or social conditions (e.g., experiences, burdens, demands, events, "stress") elicit the first occurrence of a disorder or problem under the possible influence of an individual vulnerability.

(iii) *Maintaining factors:* False responses (by the subject or its environment) or lasting demands prevent the quick reduction of the complaints and make the problem chronic.

This "three-factor model" (Margraf, 1996) is not meant to be an all-inclusive explanation of mental disorders. Instead, it is seen as a heuristic to help etiological research, the judgment of possible starting points for therapeutic change, and the formulation of individual models of pathogenesis.

The three classes of causal factors can coincide or differ completely, they can be more or less accessible to change, etc. For instance, predispositions frequently cannot be changed or problem-evoking traumata typically cannot be undone. The modification of maintaining factors in contrast is often the central mechanism of change for future well-being. Behavior therapy therefore addresses exactly this point (e.g., reduction of avoidance behavior in phobias, training of social skills in schizophrenic or depressed patients).

6.02.2.6 Typical Therapeutic Methods

One reason to conceptualize behavior therapy as a basic therapeutic orientation rather than as a single therapeutic school is the large number of often remarkably different methods that characterize the behavioral approach. Three classes of methods have to be distinguished.

(i) Basic skills that apply to the therapeutic dialogue, the therapeutic relationship or treatment motivation. Although behavior therapists in clinical practice typically display high levels of relationship skills, they neglected to present these basic aspects in their early writings. This may have contributed to the overly technical image of behavior therapy. Today it is clear that a good therapeutic relationship is typically a necessary although not sufficient condition for therapeutic success.

(ii) General therapeutic methods that do address specific disorders. These are methods that every behavior therapist has to know and that need to be incorporated flexibly into individual treatment plans. A list of these methods is given in Table 1 (left column). Several of these methods have been the backbone of behavior therapy in its early beginnings (e.g., systematic desensitization, self-assertiveness training, relaxation training).

(iii) Disorder-specific treatment programs that are tailored as much as possible to the specific characteristics of the different disorders. Such programs came later in the development of behavior therapy. Today, they have been developed and tested for most important mental disorders. Ideally, they rely upon psychological knowledge of the disorders and general change principles. Most widely disseminated are programs for various anxiety disorders, depression, schizophrenia relapse prevention, eating disorders, sexual dysfunctions or marital problems in adults, or enuresis, hyperactivity, and aggressiveness in children. A list of exemplary programs is also given in Table 1 (right column).

Most of the general and disorder-specific methods are supported by detailed treatment manuals and a sufficient body of empirical research on efficacy. The mechanisms of change are often less clear. This question forms an important focus of process research in behavior therapy.

6.02.2.7 Indications

The last important aspect that is needed for a sufficient characterization of behavior therapy are the indications or prescriptions for its application. Decisions about indication are made every day and in every type of therapeutic activity. This begins with the question whether treatment is at all indicated, continues with the choice between different treatment methods and their adaptation to the individual, and stops with the decision about termination. Indication decisions thus deal with the optimal fit between patients and treatments (and other conditions such as therapists, settings, etc.). Unfortunately, only a small proportion of these decisions are made by psychoherapists. Typically, it is the patient, his relatives, his physician, his health assurance, or other lay institutions that decide whether and what kind of psychotherapy is sought. Moreover, even in the case of psychotherapists these decions are often made in implicit or irrational ways. For example, one does what one has learned or what fits into one's therapeutic ideology. Empirically-based decisions are the exception rather than the rule in much of psychotherapy.

This situation is partly due the research problems that make a fully satifactory scientific solution of the question of differential indication impossible. The most popular version of this question was formulated by Paul (1966, 1967) as early as 1966: "which is the most effectice treatment for this individual with this specific problem, by whom and under which circumstances?" A complete answer to this question would involve large experiments with factorial designs that combine all factors. Considering the number of combinations, this is illusory. On the other hand, indication decisions cannot be avoided in clinical practice. Behavior therapy therefore pragmatically considers soluble partial questions. First, it is asked whether psychotherapy is at all indicated, then what type of treatment should be applied, and how it should be adapted to the individual case. For practical reasons, clinicians need to consider not only specific scientific knowledge but also sometimes untested assumptions, individual practical experience, expert or colleague opinions, and everyday practical knowledge.

In this context, a very important achievement of behavior therapy is the development of disorder-specific treatment programs (Task Force, 1995). In its beginnings, behavior therapy meant to a large degree the application of general psychological (learning) principles to the individual case. Therapeutic procedures were therefore typically described in the rather abstract terms of general principles. Over the course of time, procedures were described in more concrete details. This led to the development of treatment manuals which were written for groups of patients rather than for individual cases. After its publication in 1980, the *Diagnostic and statistical manual of mental disorders* (3rd ed., *DSM-III*) and its succesors rapidly became the the basis for grouping patients. Standard programs for diagnostic groups often proved very efficacious in empirical testing. Thus, modern behavior therapy has two bases for its decisions: the general characteristics of the disorder and the individual characteristics of the patient.

The pragmatic approach of behavior therapy to the difficult issue of differential indication can thus be summarized as follows: for specific disorders or problem constellations those methods should be preferred whose efficacy

Table 1 Overview of typical cognitive-behavioral treatment methods.

General methods	*Disorder-specific programs*
Exposure-based methods	Agoraphobia
Systematic desensitization	Social phobia
Flooding	Specific phobia
Response prevention	Panic disorder
Operant methods	Generalized anxiety disorder
Positive reinforcement	Obsessive-compulsive disorder
Extinction	Post-traumatic stress disorder
Response cost	Depression
Time out	Anorexia nervosa
Token economies	Bulimia nervosa
Cognitive methods	Obesity
Self-instruction training	Hypochondriasis and health anxiety
Problem-solving training	Somatization disorder
Modification of dysfunctional cognitions	Somatoform pain disorder and chronic pain syndromes
Reattribution	Schizophrenia
Analysis of erroneous logics	Sexual dysfunctions
Decatastrophizing	Marital problems
Modeling	Hyperactivity and attention deficit disorder
Social skills training	Aggressiveness
Self-control methods	Autism
Self-observation	
Self-reinforcement	
Stimulus control	
Multimodal therapy or broad-spectrum therapy	

has been validated empirically. Based on a detailed problem analysis and the course of treatment, standard interventions should be adapted to the individual case. This should take individual strengths and weaknesses, personality, life situation, and setting variables as well as possible interactions of these factors into account. The decision to apply a specific treatment program presupposes competence in the diagnosis of disorders and the analysis of problem constellations. The mutual completion of classificatory diagnosis and problem analysis is therefore the basis for rational indication decisions in behavior therapy. The explicit question for the optimal therapeutic method for a given disorder as well as the offer of concrete alternatives for disorder or problem-oriented indication decisions are specific characteristics of modern behavior therapy. Examples of the various mental disorders for which treatment programs have been developed can be taken from Table 1 and Table 3.

6.02.3 HISTORICAL DEVELOPMENT OF BEHAVIOR THERAPY

6.02.3.1 Situation at Onset and Precursors

Knowledge of the past may help understanding of the present. Behavior therapy evolved from the application of the principles of experimental psychology to clinical problems (Kazdin, 1978; Schorr, 1984, 1995). Its growth was closely related the development of clinical psychology as an applied science. Although there had been sporadic early clinical applications of psychology (e.g., the case of "little Peter" [Jones, 1924a, 1924b] or the early treament of enuresis [Mower & Mower, 1938]), a broad movement started only in the middle of the century when two conditions came together:

(i) The enormous productivity of basic research on learning theory explications for clinical phenomena had become obvious (e.g., Mowrer's two-factor theory of phobias, research on experimental neurosis, Solomon and Wynne's work on traumatic conditioning, Dollard and Miller's experiments on originally psychoanalytic concepts). These findings demanded for clinical application and testing.

(ii) There were strong criticisms of the low efficacy of the then available psychotherapeutic (i.e., psychoanalytic) methods and their poor empirical basis (e.g., Eysenck's criticism of psychoanalysis [Eysenck, 1952]). Such a fundamental critique immediately posed the question of alternatives. These of course were regarded especially critically by those who had been attacked before and thus received particular attention.

It was at this time that research groups in South Africa, England, and the USA at first independently reported great successes with learning theory-based methods in the treatment of anxiety and other clinical problems. Together with the two other named conditions these startling outcomes of the new, at first experimental methods gave the impulse for a development whose breadth and dynamic until today have no parallel in psychotherapy.

6.02.3.2 The "Founding Period"

While England and the USA are widely regarded as the origin of behavior therapy, the contribution of South Africa is still underestimated although this is where many of the founding personalities of behavior therapy started their careers. The first publication of the term "behaviour therapy" in a scientific journal took place in the *South African Medical Journal* (Lazarus, 1958). Since the end of the 1940s and during the 1950s Joseph Wolpe tried to bring together learning theory and neurophysiology at the University of Witwatersrand. This was consistent with his training as a physician with central interest in learning psychology. Wolpe had been influenced by the American work of Masserman on experimental neurosis and by Salter on "self-assertiveness training." In South Africa he worked with psychologists such as Stanley Rachman and Arnold Lazarus who together with their compatriotes G. Terence Wilson and Isaac Marks belong to the most prominent founders of behavior therapy. In such groups experimental research was discussed and therapy sessions were "supervised" and observed through one-way mirrors.

In his research on "experimental neurosis" in cats, Wolpe developed new techniques to eliminate experimentally induced fear and avoidance. Based upon the notion that conditioned fear and food intake should be antagonistic and thus inhibit each other reciprocally, he assumed that feeding could be used to reduce fears resulting from specific situations. Wolpe demostrated this successfully in his animal subjects by systematically decreasing the distance between the feeding place and the place where fear had been conditioned using electric shocks. In an article entitled without modesty *Reciprocal inhibition as the central basis of psychotherapy*, Wolpe (1954) postulated reciprocal inhibition as a universal principle: "Fear reduction is achieved if fear inducing stimuli are presented together with stimuli that produce a dominant antagonistic response to fear (i.e., reciprocal inhibition)." To make certain that inhibition was stronger, he presented fear-inducing stimuli with increasing intensity, that is, in hierachical order ("fear hierarchy").

In extending his results to humans, Wolpe primarily considered three response domains for reciprocal inhibition: sexual, assertive, and relaxation responses. Most widely employable seemed a modified version of Jacobson's (1938) progressive muscle relaxation. Wolpe believed relaxation and eating to lead to similar neurophysiological effects. In order to reduce fear responses by reciprocal inhibition, Wolpe first taught his patients progressive muscle relaxation and then encouraged them to go through their feared situations step by step while staying in the relaxed state. Originally Wolpe used exposure *in vivo* (i.e., in real life situations), but then he employed imagined situations (*in sensu*) because these were easier to realize and were better controllable. In addition, patients completed comprehensive homework *in vivo* (i.e., practiced in their natural environment) between therapeutic sessions. He called this approach "systematic desensitization" and described it in his classical book *Psychotherapy by reciprocal inhibition*, (Wolpe, 1958) that was published by Stanford University Press in the USA after a recommendation by Albert Bandura. Systematic desensitization probably still is the most famous treatment method in behavior therapy, although there are now more effective methods for many clinical problems and reciprocal inhibition theory has been shaken by contradicting evidence. Wolpe's formulation of a theory on the basis of testable hypotheses with the goal of clearly defined treatment strategies for minutely described clinical applications had a tremendous impact on the development of behavior therapy.

Many of the important actors of the South African behavioral scene pursued their work in the United States and England. Wolpe's publications came at a time where the efficacy of the psychoanalytic approach was severely attacked. Especially Eysenck's (1959) controversial argument that the success rates of psychotherapy (then largely identical to psychoanalytic therapy) were not better than spontaneous remission, that is, the percentage of improved patients was not higher with psychotherapy than without it, yielded vehement debates. It is not surpsing then that Eysenck's department was the European cradle of behavior therapy. Head of the famous Institute of Psychiatry at the Maudsley Hospital in London was Aubrey Lewis, a strong advocate of the relevance of psychological research for psychiatry. In 1950 he made Eysenck the first head of a psychological department of this leading institution. Soon collaborators such as Gwynne Jones, Victor Meyer, Aubrey Yates, or M. B. Shapiro were interested in the application of conditioning theories to psychological problems. This group knew Wolpe's publications more than the operant work of Lindsley in the USA. Single case experiments and theoretical seminars that were at first purely diagnostical were soon extended to therapeutic topics. As early as 1957 Meyer emphasized the importance of a good relationship between therapist and patient for exercises *in vivo*.

The first clinical application of a behavioral approach at the Maudsley Hospital occurred more or less by chance (Schorr, 1995). When drinking coffee with a medical student, Gwynne Jones and M. B. Shapiro discussed a patient that had been treated psychotherapeutically without success. The young dancer was unable to work because she had to urinate very frequently which had in the meantime led to secondary anxiety responses and a lack of self-confidence. The conversation led to the idea to attempt a new treatment approach using conditioning techniques. A combination of systematic desensitization *in vivo* for the main complaint and a stepwise training *in vivo* for the other anxiety responses outside of the hospital brought a treatment success that proved durable at five-year follow-up (Jones, 1956, 1960).

In the 1960s the application of learning-based treatments was advanced at the Maudsley Hospital by Rachman, who had before worked with Wolpe and now had good contact with the psychiatric side of the Maudsley (personal communication by H. J. Eysenck, September 1995). Rachman played a central role in the development of aversion therapy (Rachman & Teasdale, 1969) (which was soon to be given up again), behavioral medicine, and the treatment of obsessive-compulsive disorder (Rachman & Hodgson, 1980). Other colleagues in hospitals in London and Oxford (Warneford Hospital) such as Gelder, Marks, and Mathews developed and tested exposure treatments for phobias. At the same time American researchers such as Davison (1968) investigated the process of desensitization and other anxiety reduction techniques in detail. They came to the conclusion that exposure *in vivo* was the most important and effective component of treatment (see also Kazdin & Wilcoxon, 1976). An important reason why behavioral approaches gained influence in the treatment of anxiety-related problems so fast was the fact that their efficacy was tested systematically in controlled studies. One such study that set standards for psychotherapy research was presented by Paul in 1966.

In addition to the treatment of anxiety, such diverse problems as writer's cramp, tics, and stuttering were addressed. An important element were the publications by Shapiro (1961) on experimental single-case methodology. Clinical single-case experiments typically involve a series of measurements of a clinically relevant variable in regular intervals (time series). At a predetemined point in this series an intervention is made and the effect of this intervention is then assessed by looking at the changes in the measured variable. In this way, the effects of most intervention strategies can be determined. Later, complex experimental designs were developed (see Barlow & Hersen, 1984) that made it possible to apply single-case experiments to a large number of clinical and scientific problems as a part of everyday work. Although this method is not limited to the behavioral approach, it has a close tie to it and plays an important role in its ongoing development.

At the end of the 1950s and the beginning of the 1960s behavior therapy offered already a broad scope of therapeutic methods on the basis of experimental psychology. These became fast known outside the inner circle of active researchers. Important for the dissemination were publications and the international appointments of "founding personalities" to universities and clinical institutions. The volume *Behaviour therapy and the neuroses* edited by Eysenck in 1960 already included contributions from the USA, the UK, South Africa, and Czechoslovakia. In the early 1960s, Wolpe, Lazarus, and Cyril Franks accepted professorships in the USA. In 1963 Eysenck founded the journal *Behaviour Research and Therapy*, whose editor later became Rachman. At this time the new movement became known under the name "behavior therapy," although alternative terms (e.g., "behavior modification" which was preferred by the promoters of operant methods) existed and some prominent participants simply wanted to add explanatory elements to the traditional "psychotherapy" (e.g., Wolpe's "psychotherapy by reciprocal inhibition").

It is hardly possible to determine who really first coined the term behavior therapy. This is primarily due to the fact that there was no single "founding father." Instead, the behavioral approach developed as a relatively broad movement simultaneously in several places in South Africa, England, and the USA. For the same reason, only a starting period but not a single starting date can be given. The development as a broad movement based upon empirical psychology differentiates behavior therapy from all other forms of psychotherapy. These were regularly "invented" by single charismatic personalities with more or less distance to scientific psychology. It may be argued that behavior therapy's type of origin already contains the nucleus for the development of a broad "basic orientation" rather than a narrow "therapy school." At the same time this origin can also be seen as an important protection against dogmatic immobility and as an impetus for continuous development. Better than the invention of the term, its dissemination can be attributed. Its widespread usage goes back primarily to Hans J. Eysenck and Arnold Lazarus. While Wolpe rejected such a "brand name," they postulated that the large differences to the traditional approaches should be underlined with a new name. The first printed appearance of *Behaviour therapy* was authored by Lazarus in 1958. The first public usage of the new term, however, was made by Eysenck in a talk entitled *Learning theory and behaviour therapy* (published in 1959). Here, the highly confrontative marketing strategy of Eysenck is clearly visible: he combined a fundamental and partly polemical critique of traditional methods with a partly overly optimistic view of the new approach.

6.02.3.3 The Influence of Operant Approaches

The mainstream of behavior therapy at first developed outside of America where at that time the operant approach was very popular in psychology. This is perhaps one reason why the potential clinical applications of operant methods were hardly acknowledged. Another reason was the fact that operant researchers did not come out of the clinical sector. Skinner himself never worked clinically. But even those of his followers that moved into the clinical world typically did not limit themselves to it. Instead, they always saw other fields such as education, economy, or administration as important areas of applications for their methods.

In the late 1950s, Skinner and Lindsley described the potential applications of operant methods. Corresponding therapies, however, were only conducted in the 1960s and at first with children and mentally handicapped adults. The first clinical applications are related to the names of Charles Ferster, Ivar Lovaas, Donald Baer, Sidney Bijou, Leonard Krasner, Leonard Ullman, Nathan Azrin, and T. Ayllon. The "operant group" had constructed their own network of relationships and publication outlets. They utilized their proper, highly technical terminology and restricted themselves to the narrow approach of Skinnerian psychology whose clinical application they called applied behavioral analysis or behavior modification. The term behavior therapy was rejected as much as the term "patient" for the addressee of their interventions. Eysenck, Rachman, Wolpe, and their colleagues became aware of the clinical work of the American operant school only in the early and mid-1960s. Even after that communication between the two groups was rather reluctant. Integration of the operant methods into the behavior therapy movement was not unproblematic. It was only since the 1970s that the terms behavior therapy and behavior modification became regarded as more or less equivalent. Until today, a small group of strictly operant researchers have kept their own tradition outside of the more clinically oriented behavior therapy ("applied behavior analysis").

All in all, the relevance of operant methods is frequently overestimated, especially from outside behavior therapy, although they are only rarely applied as sole treatment methods. They do, however, have a firm place in parts of behavior therapy, for instance in the treatment of childhood behavioral problems, mental retardation, or chronically institutionalized patients. Studies such as those on "token economies" in long-term institutionalized mental patients underlined the importance of social reinforcement for change in general, for long-term generalization and the maintenance of desired or acceptable behaviors (Ayllon & Azrin, 1968). More recent research, however, has yielded doubts about the theoretical basis of token economies and other methods that were originally conceptualized as purely operant techniques. Thus, it has been shown that social feedback and specific guidelines for action were the most important factors in such programs, more important than the "tokens" themselves or the reinforcers they represented. In spite of this, the development of token economy programs was important beyond their immediate applications because they underlined the relevance of a comprehensive approach in rehabilitation. The usage of structured social reinforcement (e.g., praise) has been accepted more widely in clinical practice than the usage of tokens or symbols for reinforcement. Emphasizing the role of changing and structuring social interactions has for instance strong importance in the treatment of schizophrenic patients (Fallon, Boyd, & McGill, 1984; Hahlweg, Dürr, & Müller, 1994). Another very important influence of the operant approach was the acceptance of functional analysis (behavior or problem analysis). Behavior analysis in behavior therapy is based upon the Skinnerian concept of explaining behavior by studying the conditions under which it emerged. The relevance of living conditions, environmental factors, and social relationships had before been underestimated or even overlooked.

6.02.3.4 Consolidation and Broadening of Scope

With the founding of clinical/scientific societies devoted to behavior therapy a first period of consolidation of the stormy development began.

The American AABT was founded in 1966 as the Association for the Advancement of Behavioral Therapies. Later, the plural was given up and the name was changed to Association for the Advancement of Behavior Therapy. The first members of AABT came largely from two groups: first, a primarily academic group of scientist-clinicians interested in "clinical psychology as an experimental science," who had been organized in a subgroup of the American Psychological Association (Division 12, Section 3); second, a primarily clinically active group that had been influenced directly by founding personalities of behavior therapy such as Wolpe, Franks, Salter, or Reyna. Cyril Franks was elected as the first president of AABT, the vice-president was Wolpe. The council of the society consisted of equal numbers of scientists and practitioners. While AABT experienced an enormous increase in membership, the European sibling society EABT (European Association of Behaviour Therapy) was founded in 1971. The intiative for this was taken by Johannes C. Brengelmann, who had spent long years with Eysenck in England and in the USA. He returned in 1967 to Germany and became Director at the Max-Planck-Institute of Psychiatry in Munich and head of its psychological department. Brengelmann, who was the decisive personality for the development of behavior therapy in Germany and several other European countries, became the first president of EABT. Before this, individual national societies for behavior therapy had been founded in several European countries (e.g., the German society was founded in 1968 and one year later had already 450 members). The members of EABT at first came from similar sources as those of AABT, namely academic researchers and practioners with a close contact to founding centers such as London or Munich. The "official" founding of EABT took place during a congress in Munich, which was attended by 1200 participants from 14 countries.

Consolidation was also furthered by a rapidly increasing flood of research works and publications in journals or books and by the implementation of the first teaching or training centers. In the 1970s behavior therapy therefore came to a first stage of maturity while there were still many new techniques being developed, tested and refined. Toward the end of the decade, most of these treatment approaches were internationally accepted. Behavioral methods were the treatment of choice for such diverse problems as phobias, obsessions and compulsions, sexual dysfunctions, or the rehabilitation of chronic mental patients. At the same time existing techniques were further developed (e.g., shortening of the duration of exposure or relaxation treatments) and new methods were introduced or disseminated (e.g., social skills trainings in groups, behavioral treatment of depression). The treatment of sexual dysfunctions developed less from behavioral research on these disorders, but rather from the work of Masters and Johnson (1970) on the physiology of sexual responses. Even though this approach had an independent origin, it shared the emphasis on concrete operationalization of treatment strategies and on empirical testing with behavior therapy. This was the main reason for its rapid integration into behavior therapy which gives further testimony to the concept of behavior therapy as a broad basic orientation.

A significant broadening of the behavioral approach was introduced by the development of behavioral medicine. The term had originally been used by Birk (1973) to describe the application of biofeedback to medical problems. In biofeedback, patients are given immediate information about relevant changes in their physiological system (e.g., by auditory or visual feedback) in order to acquire control even of involuntary physiological responses. Behavioral medicine soon extended to a substantially larger field. Today, it encompasses all applications of psychological knowledge and techniques to purely somatic problems (e.g., burnings, tumor pain), disorders of possible partial psychological origin (e.g., irritable bowel syndrome), or risk factors (e.g., smoking, nutrition, physical exercise). Behavioral medicine has become a largely interdisciplinary movement that has developed a multitude of applications.

Another important development consisted of overcoming the narrow borders of the behavioristic heritage of the early learning theory-based behavior therapy. Strictly speaking, Mowrer's (1947) two-factor theory which was frequently used to explain phobias already contained a departure from behaviorism. The notion of negative reinforcement of phobic avoidance by anxiety reduction implied the concept of anxiety as an internal, "mental" state that was not directly observable. In addition, Eysenck and others had always accepted an influence of biological and genetic factors. Especially important for the advancement of behavior therapy, however, was the acceptance of the so-called "three-systems approach." Peter Lang, Rachman, and others (Hodgson & Rachman, 1974; Lang, 1993; Rachman & Hodgson, 1974) argued that psychological reactions and problems related to them needed to be seen as multidimensional, loosely connected responses systems acting on different "levels." The most popular classification differentiates between a subjective/cognitive, a behavioral, and a physiological level of response. Although these response systems are interconnected, they do not necessarily have to change in the same direction, at the same time, to the same degree etc., a phenomenon that has been termed "desynchrony" by behavioral writers (Hodgson & Rachman, 1974; Rachman & Hodgson, 1974).

This alternative to a uniform view of psychological problems was important because it allowed explanation of the wide variation in the symptom patterns reported by the patients. It also permitted a more systematic and precise assessment of treatment outcomes. In addition, differential outcomes could now be observed. Thus, relaxation exercises might influence the physiological aspects of a problem more readily than the behavioral or subjective problems. Moreover, the relevance of experience was more strongly acknowledged although a largely behavioristic, response-oriented language continued to be used. The threefold classification by Lang or Rachman has frequently been criticized. There is indeed no *a priori* reason to assume three levels rather than four or more response systems. Some authors argue that it would be better to distinguish between a cognitive and an affective system which would result in a four-systems approach. Other authors such as Fahrenberg (1987) pointed to the large body of findings that question the assumption of a unitarian, homogenous physiological level. Nevertheless, it was important to overcome the early monistic and one-dimensional view of human responses. Today, a "many-systems approach" with its emphasis on desynchrony is generally accepted in spite of the ongoing discussion about the best classification of response systems. In clinical practice, Lang's (1993) three-systems approach is the established (although simplified) standard.

At the end of the 1970s the usefulness of behavior therapy was widely accepted. Because researchers now no longer had to prove the general efficacy of their approach, some of them directed their attention to those patients that were not helped by behavior therapy, even when it was applied correctly. These studies culminated in the first scientific psychotherapeutic book on the failures of treatment by Foa and Emmelkamp (1983). Already in the late 1960s and early 1970s a beginning discontentment with the strict behavioristic guidelines of the early years was apparent. Especially Lazarus (1971) criticized the "mechanistic" terminology of early behavior therapy. He argued that the multitude of behavior therapy's interventions could not be explained by learning theory alone. Instead, he proposed the introduction of "broad-spectrum behavior therapy" that should include all techniques with empirically demonstrated efficacy regardless of their theoretical background. In clinical practice, this approach was accepted by an increasing number of behavior therapists. A further important development at this time was the attempt to apply behavioral methods to other mental disorders, especially depression. After Ferster (1965) and Lewinsohn (1974) had assumed that depression resulted from a lack of positive reinforcement, first treatment approaches consisted of elevating the rate of positive reinforcement. The success of this method stayed limited, perhaps because patients typically judged efforts and outcomes negatively even if they attempted to comply with the treatment regimen. This made the relevance of cognitive factors increasingly clear. The lack of satisfaction with the strictly behavioral techniques led to the attempt to add cognitive methods to them. This opened the way for a more systematic integration of these methods and for the development of new cognitive-behavioral approaches.

6.02.3.5 Integration of Behavioral and Cognitive Approaches

Lang's theory of three relatively independent response systems had strengthened the basis for the acceptance of cognitive ideas within the behavioral approach. Empirical psychology had already acknowledged the relevance of cognitive variables to such a degree that the "cognitive turning-point" had been passed by most actors. The delayed integration of the cognitive dimension into behavior therapy probably had its roots in the continuing influence of Watson's rejection of introspection and in the experiences with its abuse potential in "talking cures" of limited success. In addition, the polemical position toward other psychotherapeutic approaches that behavior therapists typically took in the founding phase made it difficult to abandon identity-producing boundaries. Bandura's work on vicarious learning, however, had directed the attention even of behavior therapists toward cognitive factors. The fact that people were able to learn new behaviors by observing the behavior of others even without being reinforced themselves transgressed traditional learning theory. Later on, Bandura developed a model of self-regulation that he termed "self-efficacy." This approach postulates that any conscious behavior change is based on the subject's conviction of its capacity to perform this concrete behavior. The rigorous empirical methodology of Bandura's work facilitated its acceptance even by researchers and practitioners who had originally been behavioristically oriented. In addition, the increasing interest in the concept of self-control had an important influence on the development of behavior therapy. People observe themselves, judge their own performance, and reinforce (or punish) themselves accordingly. On each of these levels, problems may arise and lead to clinical states such as depressed mood. Research into these phenomena led to the investigation of cognitive constructs including attribution and self-instruction.

Perhaps the first cognitive therapeutic method that gained acceptance in behavior therapy was Meichenbaum's (1975) self-instruction training. The popularity of this approach was bolstered by its simple, consistent theoretical basis and its resemblance with the operant concept of "coverants." Meichenbaum argued that behavior changes can be induced by changing the instructions that patients give themselves. Inadequate and negative thoughts should be transformed into more adequate statements. It is not by chance, that self-instruction training was first implemented in the treatent of impulsive children. The inner monologue and the thinking of these children were termed self-verbalizations and seen as equal to the coverants in operant terminology. The artifical term "coverant" was derived from "covert" and "operant" and thus denoted covert operant behavior. With the help of this terminology, mental contents were "smuggled" into the operant movement.

In contrast, independent cognitive approaches that had developed outside of behavior therapy encountered much more hesitation. Although Beck's (1967) cognitive therapy and Ellis' (1962) rational-emotive therapy originated in the 1960s, it took many years before they grew together with the behavioral movement. Until late in the 1970s cognitive and behavioral approaches were seen as separate "schools." This led to sometimes inadequate differentiations or to attempts to prove that the other school was "in reality" using methods of one's own school. It was only in the 1980s that the two movements converged and only in 1995 the first joint "World Congress of Behavioural and Cognitive Therapies" was held in Copenhagen. Integration also became obvious in the renaming of EABT into EABCT (European Association for Behavioural and Cognitive Therapies) in 1992 on the occasion of the 22nd Congress of the "old" EABT in Coimbra, Portugal. A common basis between the cognitive and the traditional behavioral movement were the methodological standards emphasizing operationalization, experimental research, and systematic testing of efficacy on the one hand and the rational, pragmatic orientation on the other. Today, cognitive, behavioral, and cognitive-behavioral treatments together form the broad basic therapeutic orientation alluded to in Section 6.02.2. There are, however, also critics of this convergence (for instance, Krasner's "paradigm lost," that eloquently mourns for the loss of the clear operant paradigm).

6.02.3.6 Continuous Development and the Future

Modern cognitive-behavioral therapy attempts a true integration of its components. It aims to help patients recognize their individual structure of distorted thinking and inadequate behavior. Systematic cognitive restructuring and carefully structured behavioral tasks are designed to help the patients in dealing with problems in both domains. In the meantime, cognitive-behavioral treatment programs have been developed for most mental disorders that occur in everyday practice. In some instances it is the behavioral part, in others the cognitive part that dominates. Moreover, a host of findings from process research points out that even in classical behavioral treatments such as exposure *in vivo* cognitive processes may contribute as central mechanisms of change.

The behavioral approach is still characterized by rapid change. One of the more important new achievements is the development of specific treatment programs for a rapidly increasing number of disorders or specific problem constellations. These are frequently represented in the form of concrete therapy manuals in order to facilitate practical implementation. Therapy manuals were originally used in treatment research as a mean to ensure treatment integrity in clinical studies. They were quickly disseminated in the practice sector, because they made therapeutic methods more concrete and thus accessible to the broad public of practitioners. Texts on psychotherapy had for a long time been overly abstract and often lacked any concrete descriptions or guidelines of what needed to be done in practice. Manuals with concrete guidelines therefore fulfilled an important need. The positive view of treatment manuals is reflected among others by the criteria for empirically validated treatments that were established by the Task Force on Promotion and Dissemination of Psychological Procedures of the American Psychological Association (APA). Their criteria see the existence of a manual as one precondition for any therapy method to be accepted as scientifically validated. Another important line of development is ongoing professionalization of behavior therapy in routine patient care and therapist training. Training issues are especially relevant in most European countries where a number of different private and public training models coexist. Several countries have passed laws regulating the practical application of psychotherapy including behavior therapy. These laws have important implications for research and practice as do managed care and health maintenance organizations in the USA.

The historical perspective shows what developments have led to acknowledgment of the benefit that the behavioral approach has for most mental disorders. The vast amount of change in the past leads to the prediction that the future of behavior therapy will also be characterized by major modifications of present methods and concepts. This is facilitated by the fact that ongoing research and development are major attributes of behavior therapy. But even in its present form the behavioral approach offers effective help for patients as well as a valuable basis for the understanding of mental disorders. The empirical basis for these assertions is the topic of the following section.

6.02.4 EMPIRICAL STATUS OF BEHAVIOR THERAPY

6.02.4.1 Problems in Empirically Approaching Efficacy

Psychotherapy research has moved from one difficulty to another: after a long period with a massive lack of empirical findings we now have the opposite problem. Largely due to the behavioral approach there are now so many studies on the outcome and process of psychotherapy that it has become hard for anyone to keep track. Aggregating findings across a vast number of different studies is a problem in itself (see below). Without any doubt behavior therapy is by far the most intensely researched type of psychotherapy (Grawe, 1992; Grawe, Donnati, & Bernauer, 1994). For behavioral and cognitive methods there have been over 10 times more published studies than for all other types of psychotherapy together (Grawe et al., 1994). Even some individual behavioral methods have been put to test more frequently than the whole group of psychoanalytic or humanistic approaches, respectively. In addition, behavioral methods have been applied to the broadest spectrum of mental disorders with typically positive results. However, such a general statement needs to be specified because "automatic" generalization across all disorders is senseless. Instead, individual disorders have to be regarded separately. Of course a larger number of studies does not necessarily imply better efficacy compared to other treatments. A more detailed assessment is thus needed although the whole body of psychotherapy research cannot be summarized here. I will therefore only briefly summarize the findings on behavior therapy.

How should treatment studies be aggregated? The most important approaches to the problem of secondary analysis used so far can roughly be classified into three groups:

(i) *Narrative summaries.* Here, the collected studies on a topic are simply interpreted more or less intuitively and a personal judgment of their outcomes is given. A severe disadvantage of this approach is its lack of objectivity. It has been shown that most people distort their judgment in the light of pre-existing biases. Moreover, the rapidly increasing number of publications makes it very difficult for any individual to have a complete overview.

(ii) *Box-score method.* Based on the justified criticisms of narrative summaries, this method attempts a more systematic and quantitative approach. It simply consists of counting the number of statistically significant effects that were obtained in the different studies. This, however, is subject to so many limitations that the approach is of dubious utility. Especially important is the problem of low statistical power in most psychotherapy studies. The difficulties in recruiting patients and conducting the studies typically result in small sample sizes that do not allow the detection of even clinically relevant effects with sufficient certainty. In addition, simply looking at statistical significance overlooks information about the strength of the effects ("clinical significance"). Moreover, it is unacceptable to give studies with widely varying methodological quality or very different outcome criteria equal weight.

(iii) *Meta-analysis.* This last problem also applies to meta-analysis, which otherwise avoids the power problem of the box-score method. Meta-analysis is at present the most objective method for aggregating findings from different studies. It starts by calculating "effect sizes" for each measure taken in each study. Effect sizes express by how many standard deviations the mean of two groups (e.g., treatment and control group) or of one group at two times (e.g., pre- and post-therapy) differ. This standardization makes different measures directly comparable, even across separate studies. In a second step, all calculated effect sizes are then averaged to yield one "integrated" effect size as a global index of therapy outcome. As stated above, a criticism is that the methodological quality of the studies or even clinical relevance (e.g., clinical vs. analogue sample) typically are not taken into account. Of course, one could introduce weights for methodological quality or set methodological criteria for inclusion into the meta-analysis. However, this introduces, a subjective element and thereby affects objectivity that together with its quantitative nature is a great advantage of the method. The utility of meta-analytic results has been challenged by referring to the fact that frequently very different studies are thrown together ("comparing apples and pears"). In spite of these criticisms, meta-analysis has established itself as an objective statistical method for the aggregation of heterogenous findings across separate studies.

6.02.4.2 Results of Outcome Research

The most comprehensive and differentiated analysis of outcome research so far has been published by Grawe and co-workers (1994). Shortly after this work appeared in print, it became a standard for any discussion of the topic. In contrast to earlier meta-analyses, Grawe et al. analyzed the methodological quality of the studies, took the different types of outcome measures into account, and included all controlled studies published until 1983 regardless of language, country of origin, or publication outlet in their thorough analysis. Table 2 shows the number of controlled studies that Grawe found for the different classes of therapy methods and for the individual cognitive-behavioral techniques. Table 3 shows for what types of disorders behavioral methods have been tested.

In these studies, behavioral methods have proved effective in achieving the immediate goals of treatment as well as generalized benefits that most of the individual techniques have to be given the status of empirically validated therapy methods (Grawe, 1992). Especially well researched are exposure techniques that were frequently applied to agoraphobia, obsessive-compulsive disorder, and specific phobias. They led almost always to massive improvement of the target symptoms, while the effects on general well-being and other masures were somewhat smaller. Well established is also the effect of systematic desensitization in treating anxiety disorders. A very broad range of effects was found for social skills training that almost regularly achieved significant positive changes beyond the target symptoms. Broad efficacy was also found for cognitive methods such as Beck's treatment for depression, rational-emotive therapy, Meichenbaum's self-instruction, and stress-inocculation trainings or problem-solving treatments. Studies revealed not only a very broad range of clinical applications but also some degree of specific relations between certain treatments and individual disorders. Thus, anxiety disorders were most frequently treated with exposure-based methods followed by systematic desensitization and cognitive methods. "The application of behavior therapy in clinical practice is thus based on a broad spectrum of treatment

Table 2 The number of controlled studies that were found by Grawe et al. in their meta-analysis of published therapy outcome studies.

Different types of therapy	*Number of studies*	*Only cognitive-behavioral methods*	*Number of studies*
Cognitive-behavioral methods	567	Social skills training	74
Progressive muscle relaxation[a]	66	Exposure	62
Autogenic training	14	Biofeedback	62
Hypnosis	19	Systematic desensitization	56
Meditation	15	Cognitive coping methods	38
Psychoanalytic short-term treatments	27	Aversion therapies	31
Psychoanalytic therapy	12	Problem-solving therapies	25
Long-term psychoanalysis (Freud) and analytic therapy (Jung)	each 0	Sexual therapy	22
Client-centered therapy	35	Lewinsohn's therapy of depression	17
Gestalt therapy	7	Rational-emotive therapy	17
Psychodrama and transactional analysis	each 6	Beck's therapy of depression	16
Marital therapy	35	Alcoholism programs	14
Family therapy	18	Paradoxical intention	10
Interpersonal therapy	10	Broad-spectrum behavior therapy	8

[a] The classifiaction of progressive muscle relaxation is controversial. It can be subsumed under behavioral methods (of which it typically was part) or counted as a separate entity. We chose the later approach in order to give more detailed information. Other methods not mentioned in the table were either not specfied clearly enough (unspecified humanistic therapies $N = 11$, encounter-groups $N = 9$, unspecified psychodynamic therapies $N = 8$, psychodynamic therapies with drugs N = 13, eclecticistic therapies $N = 22$) or counted only 1–3 studies (music therapy, body therapy, dance/art therapy, bioenergetics, Ich-Analyse, Individual therapy (Adler), Katathymes Bilderleben, Daseinsanalyse). Because many behavioral studies used combinations of methods, the numbers in the right column do not add to the total given in the left column for cognitive-behavioral methods.

Table 3 Types of mental disorders for which behavioral methods have been tested empirically in controlled treatment studies based on Grawe's 1994 meta-analysis. For each disorder, the number of studies published until 1983 is given.

Therapeutic method	*Childhood disorders*	*Organic mental disorders*	*Substance abuse disorders*	*Schizophrenia*	*Other psychoses*	*Affective disorders*	*Anxiety disorders*	*Sexual dysfunctions*	*Disorders of impulse cntrol*	*Disorders of adaptation*	*Somatic states with psychological factors*	*V-codes for states without mental disorders*	*Additional codes*

Table 4 Results of meta-analyses comparing the efficacy of different types of psychotherapy. Because of the low number of studies, psychodynamic and humanistic methods were typically grouped together.

	Psychodynamic/ humanistic methods	*Cognitive-behavioral methods*	*Direct comparisons within one study*
Meta-analysis	*Mean effect sizes*	*Mean effect sizes*	*Difference between effect sizes*
Smith et al. (1980)	0.64	1.03	−0.49
Shapiro & Shapiro (1982)	0.40	1.08	−0.53
Nicholson & Berman (1983)	0.29	0.75	−0.44
Wittmann & Matt (1986)	0.30/0.25	0.50	
Grawe et al. (1994) (psychoanalytic methods)	0.83	1.21	only direct comparisons
Grawe et al. (1994) (client-centered methods)[a]	0.87	1.13	only direct comparisons

[a] Without the study of Angulo (1983; quoted in Grawe et al., 1994), whose results represent clear outliers (effect sizes for behavior therapy about 8, for client-centered therapy about 4, patients with obsessive-compulsive symptoms).

methods with proven efficacy. With a clear distance to other types of treatment, behavior therapy can therefore claim to have proven its effectiveness sufficiently for playing a prominent role in psychotherapeutic mental health care" (Grawe, 1992, p. 139).

In addition to the general statements on the efficacy of behavior therapy, Grawe et al. (1994) also analyzed all studies directly comparing behavior therapy with psychoanalytic, client-centered, or systemic treatments that were published until 1991. Further inclusion criteria were at least three outcome measures, at least six hours of treatment duration, similar duration ("dosage") of the different treatment conditions (unless differences were explicitly justified on a theoretical basis), and the publication of means and standard deviations of outcome measures. In this way, they found 41 studies with a total of 1401 effect sizes. The large number of effect sizes results from the great number of treatment conditions and outcome measures. The direct comparisons underlined impressively the results reported above for the behavior therapy studies: The comparison with psychoanalytic (19 studies, 215 outcome measures, 487 individual comparisons), client-centered (10 studies, 133 outcome measures, 723 individual comparisons), and family-therapy methods (3 studies, 18 outcome measures, 40 individual comparisons) always yielded a clear-cut superiority of behavioral approaches. These results are in line with those of earlier meta-analyses as can be seen in Table 4. This table summarizes the effect sizes that have been calculated in the different meta-analyses. Because the calculatory basis differed considerably across meta-analyses, the comparison within each meta-analytic study should primarily be regarded (thus Wittmann and Matt (1986) included only German-language publications that were in addition analyzed with a different algorithm; Grawe et al. (1994) analyzed only direct comparisons, etc.). In every meta-analysis cognitive-behavioral methods fared better than other treatments. This result holds up after methodological problems (such as restriction to direct comparisons, consideration of different types of outcome measures, limitation to certain types of disorders, liberal or conservative inclusion criteria, etc.) have been addressed.

An important alternative to the meta-analytic approach was proposed by the Task Force on Promotion and Dissemination of Psychological Procedures of the APA (1995). Their approach takes into consideration one major criticism of most meta-analytic studies published so far, namely the neglect of the differences between the various mental disorders. It is inadequate to exclude the type of disorder treated in outcome research. The assumption that disorders as different as alcoholism, sexual dysfunctions, agoraphobia, or schizophrenia can be treated by the same method regardless of the specific characteristics of the disorder is unrealistic. The question for efficacy therefore always has to address clearly defined categories of problems or disorders. In addition, the APA Task Force considered treatment integrity. In contrast to, for instance, pharmacological treatments, psychotherapeutic approaches need to clarify what concrete actions are included under such labels as "behavior therapy" or "client-centered therapy." For this purpose the treatment manuals mentioned above are pivotal. Moreover, the criteria reflect the notion that controlled treatment studies may be the best but not the only valid source of empirical information on treatment outcomes. For long-term treatments these studies have traditionally been regarded as being hard or even impossible to perform. Single-case experimental studies offer an alternative if they fulfill basic methodological standards. Another requirement was that positive reports on a treatment's efficacy should come from more than one independent center, thus avoiding situations where the "founder" of a therapy keeps finding his treatment perfectly useful. On the basis of these and additional considerations, minimal criteria for empirically validated treatments were established. In addition, the Task Force made a difference between "well-established" and "probably efficacious" methods. The criteria are listed in Table 5. A first, still provisorial listing of treatments that fulfill the two sets of criteria is given in Table 6.

The results of the APA Task Force resemble those discussed above for the meta-analytic approach. The vast majority of treatments listed in Table 6 come from the cognitive-behavioral approach. This is even more important, because the proposal for the APA criteria which also accepts single-case studies as valid data originated from an psychoanalytically oriented member of the Task Force (1995). Using a quite different approach, this Task Force composed of members with various therapeutic orientations came to the same result as Grawe et al. (1994) or the other quoted meta-analyses.

6.02.4.3 Consequences of Research Findings

The behavioral approach therefore very clearly deserves the certificate of being the best validated psychotherapeutic orientation. In addition to the large number of studies on the efficacy of the individual treatment methods, the vast body of knowledge collected by clinical psychology and its neighboring disciplines on the etiology, diagnosis, and epidemiology of mental disorders contributes to this success. For most disorders, specific treatment programs tailored to their individual characteristics have been developed and tested. Behavioral treatments can therefore have very different contents depending on the nature of the problem to be treated. In principle, the superior empirical basis for behavioral treatments should imply that these methods should play a central role in psychotherapeutic patient care. However, one cannot derive from the research findings that behavioral methods are the only ones that should be applied. There are still no "100% methods" for most mental disorders. Even the best treatments yield a certain amount of failures. As long as this is the case, we need a broad spectrum of treatment options that address different facets of the problematic structures. Yet this does not mean that every

Table 5 Criteria for empirically validated treatments established by the APA Task Force on Promotion and Dissemination of Psychological Procedures (1995, 1998).

Well-established treatments

I. At least two good between group design experiments demonstrating efficacy in one or more of the following ways:
  A. Superior to pill or psychological placebo or to another treatment
  B. Equivalent to an already established treatment in experiments with adequate statistical power (about 30 per group)

OR

II. A large series of single case design experiments demonstrating efficacy
These experiments must have:
  A. Used good experimental designs and
  B. Compared the intervention to another treatment as in I.A

FURTHER CRITERIA FOR BOTH I AND II:

III. Experiments must be conducted with treatment manuals

IV. Characteristics of the client samples must be clearly specified
V. Effects must have been demonstrated by at least two different investigators or investigatory teams

Probably efficacious treatments

I. Two experiments showing that the treatment is more effective than a waiting-list control group

OR

II. One or more experiments meeting the well-established treatment citeria I, III, and IV, but not V

OR

III. A small series of single case design experiments otherwise meeting well-established criteria II, III, and IV

Table 6 Treatments named by the APA Task Force on Promotion and Dissemination of Psychological Procedures as examples of their criteria for empirical validation (1995).

- Well-established treatments
  - Cognitive therapy for depression
  - Behavior modification for developmental disorders
  - Behavior modification for enuresis and encopresis
  - Behavior therapy for headache and irritable bowel syndrome
  - Behavior therapy for orgasm and erectile dysfunctions
  - Behavioral marital therapy
  - Cognitive-behavioral therapy for chronic pain
  - Cognitive-behavioral therapy for panic disorder and agoraphobia
  - Cognitive-behavioral therapy for generalized anxiety disorder
  - Exposure therapy for phobias and post-traumatic stress disorder
  - Exposure and response prevention for obsessive-compulsive disorder
  - Psychoeducative family intervention for schizophrenia
  - Cognitive-behavioral group therapy for social phobia
  - Interpersonal therapy for bulimia
  - Interpersonal therapy for depression
  - Training programs for parents with behavior problems
  - Systematic desensitization for specific phobias
  - Token economy programs
- Probably efficacious treatments
  - Applied relaxation for panic disorder
  - Psychodynamic short-term therapy
  - Behavior modification for sexual offenders
  - Dialectical behavior therapy for borderline personality disorder
  - Emotion centered couples therapy
  - Habit reversal training and habit control training
  - Psychoeducational therapy of depression

therapist can do what they want regardless of the research findings. We need to ask ourselves how to choose the most promising method for each individual case or for the rank order of the different approaches that could possibly be applied to the case. These decisions need to take into account other variables such as the motivation and personality of the patient, the possible existence of comorbidity, or the availability of treatments or therapists. In addition, it has to be clarified whether and when the patient should be transferred to another specialist and what role primary care physicians and self-help measures could play. As a general rule, measures with the best cost-benefit ratio should be tried first. These considerations lead to the proposal of more or less rational "sequential models" for clinical practice (Margraf, 1996) such as the one detailed in Table 7. Of course, the model delineated below represents an abridgement, that in clinical practice needs to be specified according to disorders and other factors.

The ideas behind this sequential model can be summarized as follows.

(i) It is generally better if the patient is able to solve his problems himself. Therefore, given an adequate motivation the person should be encouraged to try self-help measures. The input of lay personnel such as relatives or friends also belongs here.

(ii) If self-help fails or is insufficient, however, professional help should be sought. Here we can distinguish between general, nonspecific counseling or supportive measures on the one hand and a specfic therapy for the mental disorder on the other. As long as there are no acute crises, suicidal ideation, active psychoses, or a long history of failed treatments, generalists such as the family physician can try to achieve improvement using nonspecific measures.

(iii) If this does not lead to clear-cut improvement or the listed conditions are not met, a specific treatment of the mental disorder should be started as fast as possible in most cases, beacuse most mental disorders otherwise have a high risk of chronification. The decision between the competing psychological or pharmacological treatments should not simply be based on the personal preference of therapist or patient. Instead, it should consider probability of success, cost-benefit ratio, durability of treatment outcomes, and the other conditions discussed above (e.g., availability).

(iv) Among psychological treatments, cognitive-behavioral methods should typically (for most disorders) form the first line of

Table 7 A sequential model for choosing treatment interventions in clinical practice.

1. Self-help, lay interventions
2. Advice, counseling, supportive therapy
3. Specific treatment of the mental disorder
    3.1. Behavior therapy
    3.2. Other psychotherapeutic and pharmacological interventions
    3.3. Long-term interventions after treatment failures

Source: Margraf (1996).

intervention because their efficacy is best validated and they have a favorable cost-benefit ratio. Only if this does not lead to sufficient success should other types of psychotherapy be applied because these typically are less well established empirically and often involve greater expense (e.g., longer duration).

(v) Similar considerations apply to the choice of pharmacological methods. Here, the questions of durability of outcomes or relapse after drug withdrawal and of side effects (cost-benefit ratio) may lead to critical reflections.

(vi) In some cases, the necessity of long-term support may arise. This could for instance be the case if intensive attempts have not led to clinically significant improvement. Here its is important to convey to the patient that he or she is not alone and to avoid making the patient "guilty" for failure. Of course, it needs to be clarified whether all promising treatment methods have been attempted competently. In clinical practice, one frequently sees cases where due to their training or theoretical orientation, care providers used only a narrow part of the total spectrum of treatment methods. In these cases, transfer to another specialist is often helpful. In other cases, however, all that is left is to convey to the patient a realistic notion of his chances for recovery and to support him in dealing with the chronic aspects of his condition.

6.02.5 PROBLEMS AND CRITICISMS OF BEHAVIOR THERAPY

Like any other human endeavor, behavior therapy has its share of problems. These are for instance the treatment failures that may occur even with good motivation on the patient's side and optimal application on the therapist's side. Here, research is called for in order to ameliorate success rates, attrition, etc. Other important problems of behavior therapy lie in limiting setting factors such as lack of information of patients and professionals or obstinate misunderstandings about the behavioral approach. In addition, the availability of well-trained behavior therapists is a major problem in most parts of the world, even in those countries where the behavioral movement started. Moreover, it is very difficult for patients or other physicians or psychologists to judge the competence of any given colleague. Many national health insurance schemes (or the lack of them) are responsible for limitations to the availability of competent behavior therapy. Another aspect are the wishes and prejudices of the patients that often come with strong feelings about their treatment. These are frequently conveyed by media, popular literature, friends, or relatives. Some decline any notion of pharmacological help ("how can pills help with psychological distress?"), others definitely do not want to be treated by psychotherapy ("I am not crazy!," "They only dig in the past!"). Some people, especially with an academic background, have powerful convictions even with respect to the specific kind of psychotherapy ("in depth," "thorough," "explain everything"). All of these points together may be responsible for the fact that behavior therapy is applied far less frequently than one should assume on the basis of the research findings and the productive publication activities of its proponents.

6.02.5.1 Misunderstandings About Behavior Therapy

An important obstacle to the dissemination of behavioral methods have been several obstinate misunderstandings about its nature or techniques (Baer & Minichiello, 1990; Yates, 1977). Some of these misconceptions will be briefly addressed here.

(i) Behavior therapy does not lead to symptom substitution.

(ii) The experience of strong emotions during exposure (e.g., in phobias, grief reactions, post-traumatic disorders, or eating disorders) is not dangerous for the patients.

(iii) The thoughts and feelings of the patients are not ignored. Instead, they are addressed directly by a multitude of therapeutic interventions.

(iv) Modern behavior therapy does not assume that all mental disorders have been acquired by simple conditioning processes.

(v) The use of medication is not generally incompatible with behavioral interventions.

Inasmuch as these misunderstandings are being clarified and together with the mounting reception of the results of psychotherapy research, a growing interest in behavioral methods can be observed. But even today, the lack of well-trained specialists is a major problem.

6.02.5.2 Scientifically Well Established, Practically Neglected?

A remarkable example of the underutilization of behavioral methods is given by the treatment of anxiety disorders. If anything, these disorders should be a primary area of application for behavioral methods. However, procedures such as exposure *in vivo* are apparently given only to a small minority of afflicted persons. Taylor et al. (1989) studied a large sample of patients with anxiety disorders that had applied for treatment to the anxiety disorders clinic at Stanford University School of Medicine. Although the region surrounding the clinic was densely populated with care providers, they found that less than 10% of agoraphobic patients had been given a trial of exposure.

One criticism of this study can be seen in the fact that the nonrepresentative sample consisted of self-selected patients searching treatment. However, we recently found the same effect in a sample 3000 people representative of the German adult population (Margraf, 1996; Margraf & Poldrack, in press). The study investigated the prevalence of clinical anxiety in the general population using the Beck Anxiety Inventory using a cut-off score from clinical anxiety research. In face-to-face interviews, subjects who reported anxiety were asked whether (and if so, how) they had been treated for their anxiety problem. Results showed that even with the broadest definition of treatment only 40% of all afflicted persons had received some kind of treatment and that primary care physicians were by far the most frequent care providers (82% of all treated patients). Genuine specialists such as clinical psychologists (3%) or psychiatrists (6%) together performed fewer treatments than other somatic physicians (17%, multiple responses possible). With respect to the treatments used, there was a remarkable discrepancy between drugs (roughly 90% of all patients, multiple responses possible) and nonspecific advice (roughly 75%) on the one hand and psychotherapy (17%) on the other. In addition, an elevated rate of inpatient treatment (10%) became apparent.

Yet the most impressive result to us was that psychotherapy consisted with roughly equal numbers of relaxation methods (including hypnosis and autogenic training) and "talking cures" (i.e., primarily psychoanalytic or client-centered methods), while cognitive-behavioral methods accounted for only 1% of all treatment cases. In view of this fact, it may seem less surprising that patients on the whole were not very satisfied with their treatment successes. For any type of treatment, the proportion reporting durable improvement was not attained even in one-third of respondents. The lowest success rate was given for psychotherapy with only 14% of respondents reporting lasting success (compared to 29% for drugs!). Of course, these results are limited by the fact that they are based on the patients' classification of the treatment received. However, assessment of treatments was not simply limited to giving labels such as "behavior therapy" or "client-centered therapy" that may be unknown to many patients. Instead we gave brief descriptions of various treatment methods (e.g., "exposing yourself systematically to feared situations or objects"). In any case, this study makes it possible to generalize from the findings from patients seeking treatment to the general public.

6.02.5.3 Current Criticisms of Behavior Therapy

In addition to the problems caused by misunderstandings, misapplications, or the lack of application, there are several criticisms that apply to behavior therapy in its current form. In my opinion, behavior therapy at least partly has not addressed some of these criticisms well enough, which should make its proponents more modest.

(i) Theory and practice frequently do not overlap very well (Eysenck & Martin, 1987; O'Donoghue & Krasner, 1995). For instance, exposure methods have a well-established efficacy in the treatment of phobias, but the theory upon which they are based (two-factor theory, habituation) are outdated in their classical form. In the same vein, functional behavior analysis classifies problematic into operant and respondent types although it is quite clear that most clinical problems are neither one nor the other.

(ii) Because its treatment methods are most often disorder-specific and rely strongly on the empirical knowledge about these disorders, behavior therapy has neglected unspecific or diffuse complaints or problem constellations. The guidelines for dealing with the problem of comorbidity (common occurrence of more than one disorder, which is the rule rather than the exception) are sparse and often unsatisfactory.

(iii) There are hardly any approaches to the problems of counseling, although this forms a large part of the work not only in couseling centers but (to a lesser degree) also in psychotherapy. How should one work through inadequate feelings of guilt after separation, deal with leaving-home situations, educational problems, existential problems, etc.?

(iv) The strong emphasis on change together with the explicit induction of hope for improvement has not only positive consequences because there are limits for change and some situations should not not be changed at all (Wilson, 1996). An example of this problem is behavioral marital therapy. Not all partnerships can be optimally restructured, even in well-functioning partnerships there may be instances where the partners do not agree and that should not be changed. There is a danger of promising too much or things that cannot be attained (see the discussion of therapeutic goals in Section 6.02.2.3).

(v) The "classical" criticism of early behavior therapy, namely the neglect of experience compared to an overemphasis on behavior, does not apply to modern cognitive-behavioral approaches. It is, however, justified for those forms of behavior therapy that have not passed the "cognitive turning-point."

6.02.6 CONCLUSIONS

This representation of the behavioral approach has attempted to give a satisfactory answer to the nature of this therapeutic orientation by describing its past and present and simultaneously trying to stay open to future developments. The close relationship between research and practice has always been a special advantage of the behavioral approach. It is to be hoped that this will not be lost as behavior therapy becomes a more and more professionalized endeavor. In psychotherapy we stand in front of the remarkable fact that we have a far from satisfactory state in practical patient care and at the same time highly effective methods to ameliorate this situation. We should not let ourselves be kept from bridging this gap. Problems such as the lack of application of successful methods, the widespread misallocation of resources, and the strong need for high-quality psychotherapy point to urgent tasks for the health care system:

(i) disseminate knowledge about already available methods;

(ii) ameliorate the conditions for their implementation;

(iii) ameliorate the assessment of mental disorders;

(iv) develop simple interventions for routine care by nonspecialists;

(v) develop prevention programs; and

(vi) routine evaluation and quality assurance.

In dealing with these challenges we need to avoid the two contradictory dangers of trivializing or medicalizing psychological problems. Many psychological problems of a transitory or clearly subclinical nature should not be medicalized, that is, they should not be declared "illnesses" requiring treatment ("for every bad feeling a therapy"). On the other hand, full-blown mental disorders may not be trivialized and thereby be withdrawn from adequate and necessary treatments ("depressed people simply need to get their act together"). As a rule, all concerned parties will only profit from a movement away from ideology and toward a more empirical approach in psychotherapy. Hopefully, the current debates on psychotherapy research will contribute to that process.

6.03.1 INTRODUCTION

Nearly 40 years have elapsed since the early work of Beck and Ellis in the late 1950s and early 1960s in cognitive approaches to the treatment of emotional disorders. Both were reacting against classical psychoanalysis in which they had been trained and thus started what has been termed "The cognitive revolution" (Dember, 1974) which, however, is probably best conceptualized as an evolution from the two embattled camps of psychoanalysis and behaviorism (Blackburn, 1986; Salkovskis, 1986).

As with all "new" ideas, the cognitive movement did not arise *de novo*. Several influences within the general field of psychology and from clinical practice have been acknowledged, in particular Piaget (1972) who described the hierarchical structuring of knowledge; the ego analysts (e.g., Adler, 1936; Horney, 1950) who stressed patterns of thinking regarding the self and the world as central to understanding feelings and behavior; Kelly (1955) who was a real ancestor in his descriptions of personal constructs; Arnold (1960) and Lazarus (1966) who stressed the role of cognition in their theories of emotion.

Be it revolution or evolution, it can certainly be asserted that cognitive therapy has been a most successful movement, in view of the highly prolific research literature, the number of specialized journals, the demands for training courses in cognitive therapy, and continuous refinement of the underlying theoretical principles. The strength of cognitive therapy from its inception has been its emphasis on empirical backing. This tradition continues, both in experimental studies and in clinical outcome studies, and, consequently, the theory has not remained static, being also informed by advances in related areas of study, namely cognitive science, social science, and biology.

This chapter will consider the key principles of the cognitive theory of emotion and how they apply to cognitive treatments. The range of approaches and recent developments will be discussed.

6.03.2 PRINCIPLES OF COGNITIVE THEORY OF EMOTION

6.03.2.1 A.T. Beck (Early Model)

Beck's early work (1963, 1967), related to thinking style in depression and later expanded to other emotional disorders (1976). He described the typical negative content of thought in depression as a pervasive negative view of the self, of the environment, and of the future (the negative cognitive triad), expressed in automatic, habitual thoughts in reaction to trigger stimuli. The negative automatic thoughts are maintained by various processing errors with a negative bias (arbitrary inferences, selective abstractions, personalizations, overgeneralizations, minimizations, and magnifications). These processing errors do not differ necessarily from the type of processing errors made by nondepressed individuals (labeled heuristics by Kahnneman, Slovic, & Tversky, 1982), the difference being in the direction of the bias, which is usually positive in the nondepressed, expressed as a self-serving bias (Taylor & Brown, 1988). The consequence of processing information with a negative bias is a congruent negative emotion. Thus, the information processing model of emotional disorders was set in a straightforward vertical or unidirectional model, which has since been reviewed. To explain why some individuals process information with such unhelpful biases, Beck evoked the concept of basic structures or schemata derived from cognitive science (Bartlett, 1932; Neisser, 1976; Piaget, 1950) These represent the sum of previous experiences, serving as templates that direct attention, influence encoding and interpretation of stimuli, and facilitate recall. In depression, the schemata reflect themes of loss and of self deficiency, for example, "unless I do everything perfectly, I am worthless" or "unless I do everything to please others, they will reject me." It is noteworthy that at this stage of the theory, no differentiation was made between conditional schemata or basic assumptions, rules, and attitudes on the one hand, and unconditional schemata or core beliefs on the other, for example, "I am inadequate" or "I am unlovable." An example linking the three elements described above would be:

Schema: (conditional)
"If people do not like me, I cannot be happy"

Stimulus:
"A friend does not telephone as promised"

↓

Interpretation: (Content of thought expressed in negative automatic thoughts)

"She does not like me"	(*arbitrary inference personalization*)
"Nobody likes me"	(*magnification*)
"I shall always be alone and miserable"	(*overgeneralization*)

↓

Feeling:
"Down in the dumps"

Once the negative feeling is triggered, it is likely to feed forward and lead to other stimuli being interpreted negatively in accordance with the schema which has been activated and which becomes progressively more widely applied to inappropriate stimuli. Similarly, maladaptive behaviors, such as ruminations and inactivity, become preponderant and increase the incidence of negative automatic thoughts and the corresponding dysthymic moods. The typical schemata, beliefs, rules, and attitudes reflect themes of love, approval, entitlement, omnipotence, perfectionism, autonomy, and achievement, as measured by the Dysfunctional Attitude Scale (DAS) which was developed specially to assess this aspect of Beck's theory (Weissman & Beck, 1978)

The cognitive model of the anxiety disorders (Beck, 1976; Beck & Emery, 1985) followed the same principles, emphasizing specific patterns of thinking which differentiate these disorders from depression. Beck, Laude, and Bohnert (1974), in two studies designed to elicit thoughts and visual imagery associated with anxiety, found that anxious patients experience threatening thoughts or images which often precede attacks of anxiety. These thoughts relate to anticipated or visualized danger and extreme vulnerability. It was apparent that imagery was important in anxiety, an aspect that had not been stressed in depression, but which is emphasized in cognitive therapy (Edwards, 1989) The content of thought in anxiety was found to relate to an anxiogenic triad; seeing the world as threatening, the self as vulnerable, and the future as uncontrollable. This approach was similar to that of Lazarus (1966) who distinguished between two cognitive processes in anxiety, namely primary and secondary appraisal. Primary appraisal relates to an individual's evaluation of a situation as dangerous and threatening, whereas secondary appraisal relates to the evaluation of the self as not having the internal and/or external resources to deal with that situation.

The processing errors in anxiety do not differ essentially from those described in depression, but the schemata are likely to be different, referring to themes of personal vulnerability, of unpredictability, and of threat, for example, "If I feel anxious, this means I have no control of myself" or "I must always be on my guard, if not something awful will happen."

As in depression, the dysfunctional schemata are self- or world-referent; they tend to be rigid and undifferentiated. These characteristics have been taken as implying that they have been learnt in early childhood and continue to survive through the process of assimilation, rather than accommodation (Piaget, 1977).

6.03.2.2 The Evolution of Beck's Model

The implications of the original model were of a causative link between cognitions and emotions, assigning primacy to cognitions. This was challenged by Zajonc (1980) and Rachman (1981, 1984). Beck (1987) restated his approach more clearly, emphasizing that negative cognitions are inherent to depression, as delusions are inherent to psychosis, and that, therefore, they cannot be conceptualized as causing depression, as delusions cannot be said to cause psychosis. Negative cognitions are one side of the coin and biological changes the other side. While research findings have given ample evidence for a negative content of thought in depression (Haaga, Dyck, & Ernst, 1991) and thoughts relating to personal danger and inability to cope in anxiety (Hibbert, 1984; Butler & Mathews, 1983), the causative role of cognitions, and the specificity of cognitive therapy, relative to antidepressants medication, in changing cognitions have not been demonstrated (Blackburn & Bishop, 1983; Simons, Garfield, & Murphy, 1984).

Regarding particular biases in information processing, in general, studies support an attentional bias in anxiety and a memory bias in depression (Dalgleish & Watts, 1990; Mogg et al., 1991; Wells & Matthews, 1994; Williams, Watts, MacLeod, & Mathews, 1988) Williams et al. (1988) proposed that "anxiety involves biased allocation of attention at the preattentive stage, and depression involves biased use of mnemonic cueing at the elaborative stage" (p. 181). Indeed, several studies have found no bias in memory for threat words in anxious subjects, *inter alia* (MacLeod, 1991; Mineka, 1992; Mogg, Mathews, & Weinman, 1987), while there is substantial evidence of a negative bias in retrieval process in depression (Blaney, 1986; Breslow, Kocsis, & Belkin 1991; Teasdale & Russell, 1983). The extensive research in information processing in depression and the anxiety disorders (reviewed by Wells & Matthews, 1994; Williams et al., 1988) directly inform cognitive therapy as applied to these disorders to date.

The structural aspect of the cognitive model of the emotional disorders has been the most elusive of its components to put to experimental validation. As alluded to above, the term "schema" has been used differently by different authors and a reliable and valid methodology to measure and assess schemata is not well established.

In the conceptualization of cases for the development of cognitive treatment strategies (Persons, 1989), it is usual to differentiate between conditional schemata or basic assumptions and core or unconditional schemata. Thus, in the example given in the previous section, the core schema may be "I am unlovable" leading to the conditional schema "If people do not like me, I cannot be happy" and the rule "I must do everything people ask of me." The same basic or core schema may lead to the conditional schema "If people get close to me and get to know me, they will reject me" leading to the rule "I must avoid close relationships". This differentiation developed from the extension of cognitive therapy to personality disorders (Beck, Freeman, et al., 1990; Young, 1990); from greater emphasis on the role of conceptualization in treatment (Blackburn, Twaddle, et al., 1996); and from the clinical observation that although there seems to be a limited range of themes in basic schemata, there is a wide variety of conditional schemata leading to different behaviors, different ways of constructing the self and the environment, different mood states, and different disorders. The typical themes of core schemata relate to personal worth (e.g., I am worthless/useless), to moral worth (I am bad/evil), to abnormality (I am a freak/abnormal/different), and to personal ability (I am incapable/inadequate). Examples of how these different levels of the structural aspect of cognitive theory are used in case conceptualizations will be given in Section 6.04.3.

The standard assessment tool of underlying cognitive structures remains the DAS, Form A, (Weissman & Beck, 1978), a 40-item, seven-point scales questionnaire which primarily is aimed at measuring the presence and intensity of belief in conditional schemata in depression. A questionnaire by Young (1990) attempts to measure core schemata (Early Maladaptive Schemata in Young's terminology), but the scale has not been validated adequately. Several studies, using the DAS, have shown that level of dysfunctional attitudes discriminates between depressed subjects and controls, *inter alia* (Blackburn, Jones, & Lewin, 1986; Hamilton & Abramson, 1983) and at post-treatment, predicts future levels of depression (Rush, Weissenberger, & Eaves, 1986; Simons, Murphy, Levine, & Wetzel, 1986). However, not surprisingly according to Beck's theory, the level of dysfunctional attitudes decreases markedly with remission and becomes indistinguishable from normal level (Blackburn, Roxborough, Muir, Glabus, & Blackwood, 1990; Simons et al., 1984).

The endorsement of self-referent adjectives is another method of assessing the self-schema (Segal, 1988), which is more in line with the definition of schemata in cognitive psychology. Using this methodology, Teasdale and colleagues (Teasdale, 1988; Teasdale & Dent, 1987) found that subjects vulnerable to depression recall more global self-referent adjectives (e.g., "pathetic," "worthless," "stupid") than never depressed subjects who recall more specific and milder negative self-referent adjectives (e.g., "rude," "thoughtless," "inconsiderate"). The number of global negative adjectives endorsed also predicted level of depression five months later in mildly depressed women. Teasdale (1988) put forward his differential activation hypothesis on the basis of such findings; this states that the type of thinking activated in mild-dysphoric moods, in combination with high neuroticism, a personality variable (Eysenck, 1970) which also affects selective recall of depressed memories, is likely to activate higher levels of depression. These globally negative self-referent adjectives are likely to reflect core schemata. Figure 1 describes the generic model of the emotional disorders, following Beck's approach as developed from the original model, differentiating core schemata and basic assumptions. In Figure 2, the application of the generic model to a specific case is shown in a case formulation, where good as well as depressed periods can be understood through the individual's core schema.

6.03.2.2.1 Personality variables

A further development in the area of vulnerability to depression has been the delineation of higher-order, more stable personality characteristics which may determine the content of dysfunctional schemata. These have been defined as sociotropy and autonomy by Beck and his colleagues (Beck, 1983; Beck, Epstein, & Harrison, 1983). An overly sociotropic individuals is described as socially dependent, highly invested in positive interchange with others, valuing above all acceptance, intimacy, support, and guidance. In contrast, an overly autonomous individual is highly invested in independent functioning, mobility, freedom, choice, achievement, and the integrity of the personal domain.

A specially constructed scale, the sociotropy-autonomy scale (SAS; Beck et al., 1983) consists of 60 items rated on five-point scales. A large number of studies have been conducted (Blackburn, 1996; Clark & Beck, 1991; Gilbert & Reynolds, 1990; Hammen, Ellicott, Gitlin, & Jamison, 1989; Moore & Blackburn, 1994; Robins, 1990) indicating that sociotropy is related to vulnerability to interpersonal life events, to level of depressive symptoms, to level of neuroticism, and to the subscale of the DAS which measures social approval. Moreover, Moore and Blackburn (1996) have shown, in a large clinical sample of depressed patients assessed pre- and post-treatment, that sociotropy, as assessed by the SAS, is relatively stable over time in contrast with level of dysfunctional attitudes as assessed by the DAS. On the other hand, the conceptual validity of autonomy has not been demonstrated. It has been shown to be only minimally related to level of depression (Gilbert & Reynolds, 1994; Moore & Blackburn, 1994, 1996), to correlate poorly with other measures of independence and not to predict consistently an interaction with negative achievement events (Hammen et al., 1989; Robins & Block, 1988). The autonomy scale of the SAS is in the process of being revised for new validation studies (Clark, Steer, Beck, & Ross, 1995).

"I am inadequate."
(Core schema)
Works hard at school, university and at keeping a tenuous relationship going.
Has cheated in an examination – guilt.
"This is shameful;
I'm not as good as Ann."
Takes an "easy" subject at university. The "better" students study medicine or science.
"I am not good enough."
Depression:
Examination time –
"I won't pass, I'm not good enough."
Breakdown of relationship.
Depression:
"I have failed."
"I've put in all this effort for nothing."
"I feel dumped, abused."
"Cannot let anybody know."
Marriage, good job:
Feels happy.
Depression:
New job/difficulties at work.
"I thought I was doing well, they don't value me – I'm no good."
"All my efforts have come to nothing."
Improved work conditions:
Feels good.
Change of job:
Feels deskilled/devalued.
"I'm no good."
"I can't cope."
"It's my fault."
Depression:
This is shameful.
"I should be able to cope – if not people will look down at me."
"It is shameful to be seen as not coping."
"I must be well organised and keep everything under control – if not I'm failing."
"If my personal relationships go wrong, it is my fault."
(Basic assumptions; conditional schemata)

6.03.2.3 Interpersonal Processes

It may be that the relationship of sociotropy, and not autonomy, to depression simply reflects that interpersonal processes are of particular importance in depression, and possibly in other emotional disorders. Early descriptions of cognitive therapy were criticized for ignoring interpersonal processes (Coyne & Gotlib, 1983). Safran and Segal (1990) have made a welcome contribution emphasizing the role of interpersonal factors. They state "the individual must always be understood as part of the interpersonal systems in which he or she is participating. Thus, one cannot understand the patients in therapy independently of the therapist" (p. 5). They view the therapeutic relationship as central to cognitive therapy, in that it is through the therapeutic relationship that core dysfunctional interpersonal schemata can be revealed. The interpersonal schema is defined as a generic cognitive representation of interpersonal events which derives from interactions with attachment figures of the past and serves to predict future interactions with these figures and with others. The stress on the interpersonal perspective has exercised a strong influence on the practice of cognitive therapy, in that more emphasis is put on the therapeutic relationship and more attention is paid to developmental factors, especially in the treatment of personality disorders. Issues which might have been considered as stumbling blocks in therapy, for example, lack of trust, overdependence, avoidance, and aggression, can now be directly employed to guide formulation and questioning. For example, if the patient appears to be aggressive in therapy, the therapist may comment: "It seems to me that you feel angry with me. Is this how you feel at the moment?" "Is it something that I have said or something about me?" "Is there some other situation like this outside of therapy that made you feel the same?" "Did this happen in your family?" Thus, the typical socratic questioning or guided discovery style of cognitive therapy is used to uncover possible core interpersonal schemata, rather than, perhaps more traditionally, just to elicit the current automatic thoughts so as to revaluate them and to look for disconfirming evidence.

6.03.2.4 Constructivism

Mahoney (1993) suggests that one of the "major conceptual developments in the cognitive psychotherapies over the past three decades" has been the differentiation of rationalist and constructivist approaches to cognition. Constructivism or constructive metatheory emphasizes the active and proactive nature of all knowing, the operation of tacit or unconscious processes, the complexity of human experiences, and the need for a developmental, process-focused approach to knowing. Some of the proponents of this approach, apart from Mahoney, are Neimeyer (1992, 1993), Guidano and Liotti (1983), and Anderson (1990) who are all indebted to Kelly's (1955) personal construct theory. Constructivism is contrasted by these authors to logical positivism and rationalism which are described as characterizing Beck, Rush, Shaw, and Emery's (1979) information processing model and Ellis' (1962) rational-emotive approach. Neimeyer (1993) considers constructivism to be predicated on a postmodern epistemology and gives a quote from Kelly (1977, p. 6) "what we think we know is anchored only in our assumptions, not in the bedrock of truth itself, and that world we seek to understand remains always on the horizons of our thoughts," as representing a quintessentially postmodern conclusion.

Neimeyer (1993) contrasts traditional cognitive theory and therapy with constructivist theory and therapy. In so doing, he gives a distorted and narrow view of the Beckian approach, at least in its modern form. He interprets Beck et al. (1979) and Ellis (1973) in particular, as equating emotional adjustment with rationality (logical empiricism), so that when humans deviate from rationality and the scientific method, they form distorted views of themselves, their world, and their future, and experience dysphoric emotions and emotional disorders. The word "rational" may have been emphasized in earlier cognitive theory, but it is not now; the term "dysfunctional" being preferred, indicating that thoughts or attitudes are dysfunctional when they have negative consequences, not because they are irrational. These changes in the theory have followed research findings that indicate, for example, that depressed subjects do not have exclusive negative thoughts (Clifford & Hemsley, 1987), that depressed subjects choose as many positive as negative adjectives as self-descriptors (Derry & Kuiper, 1981), and that normal controls show a ratio of 1:17 of negative to positive thoughts. (Schwartz, 1986). Ellis (1993) has argued that even rational-emotive therapy (RET) has never been truly rationalistic, although he accepts that he too has moved from a more rationalistic to a more constructivist position. Cognitive therapy (Beck et al., 1979) has, in any case, always used questioning that stresses the disadvantages of thinking in certain ways and the advantages of thinking in alternative ways, rather than logical vs. illogical thinking.

However, it must be acknowledged that a number of the changes in cognitive therapy, as it has evolved, have been influenced by the philosophical stance of constructivist theories. The examination of developmental factors to understand the cognitive structures through which an individual construes their world, the stress on interpersonal processes, and developments in the understanding of information-processing to explain individual emotional reaction, as described in the next section, probably reflect constructivist influences.

6.03.2.5 Information Processing and Cognitive Science

Cross-fertilization from cognitive science has inspired a vast number of ingenious experiments to test various aspects of information processing in depression and anxiety disorders, and has prompted more complex models of information processing (Ingram, 1988; Teasdale, 1993; Teasdale & Barnard, 1993; Wells & Matthews, 1994; Williams et al., 1988). Ingram and Kendall (1988, p. 13) present a complex model which is adapted in Figure 3.

These authors attempt to delineate the "pattern of relationships among the various components of the cognitive taxonomic system." The diagram indicates that the different components which may be involved in information processing operate in a reciprocal, interactional, and multidirectional fashion. Cognitive structure is defined as the architecture of the system in which information is stored and organized. This would consist of long- and short-term memories, sensory memories, and associative networks. Cognitive content represents the information that is actually stored, that is, the content of the cognitive structure, for example, semantic and episodic memory. The term schema, as used in cognitive therapy, is represented by both the cognitive structure and the cognitive proposition. Cognitive operations represent the various procedures by which information is processed, for example, attention, selection, encoding, interpretation, and retrieval. These represent the various cognitive processes which have been found to show particular biases in the emotional disorders (attentional biases in anxiety and retrieval biases in depression). Cognitive products represent thoughts, both automatic and controlled, and images. Arrows labeled as operations indicate cognitive processes leading to cognitive products, whereas arrows not labeled as operations indicate "procedures that may not be primarily cognitive," for example, the interactions between affective, biochemical, and cognitive factors.

The model suggests that behavior can be affected by a variety of sources, by cognitions, by cognitive structures directly (e.g., unconscious routines such as riding a bike), and by affective and biochemical factors. The acknowledgement of other cognitive structures, which remain undefined, recognizes that understanding of the cognitive system is still incomplete, particularly as regards unconscious structures. The model also suggests a generic model for the emotional disorders which can take into account similarities and differences across different disorders. For example, in depression and anxiety, the operation through which information is processed may be largely similar, but the content of the cognitive structures and the cognitive products differ as described in Section 6.03.2.2. Such a model would evidently be far too complex to use in therapy. Instead, as shown in Figure 4, a simplified generic model giving the same information can be given to patients (Greenberger & Padesky, 1995). The diagram indicates the interactions among all elements; biology (which includes physiological and biochemical changes), thoughts (automatic thoughts, beliefs, attitudes, schemata), emotions, and behavior and stresses that the individual exists within an environment which triggers their reactions and which reacts to their reactions.

Bower (1981) presented his influential associative network theory of mood and memory which derived experimentally to explain the relationships between cognition and mood. According to this theory, emotions, as well as cognitions and events, are represented in the brain/mind by discrete nodes or units which are linked in an associative network. Thus, an emotion can be activated by an appropriate external stimulus or by the activation of other linked nodes in the associative network, for example, a sad memory or some physical sensation. Once activated, a depressed mood or an anxious mood will influence future information processing by the spreading of activation through the associative network, so that events or situations are more likely to be interpreted negatively or as denoting threat and danger. The prediction from Bower's (1981) paper was of a recriprocal relationship between mood and thinking, so that there would be mood state-dependant retrieval (superior recall of material retrieved in the same mood state as was present during learning) and mood-congruent retrieval (increased ease of recall of sad memories when in a depressed mood state). These predictions have been confirmed in several studies using both naturally occurring depressed moods (Clark & Teasdale, 1982; Miranda & Persons, 1988; Miranda, Persons, &

Buyers, 1990) and in induced moods (Teasdale & Fogarty, 1979; Teasdale & Taylor, 1981). However, a number of disconfirming findings have also been reported, as seen in meta-analyses and Ucros (1989) and Bower (1987) concluded that his theory needed revising. Bower (1992) has expanded his theory by proposing that emotions may activate not only isolated semantic concepts, but wider rule-based action plans.

Teasdale (1993) finds Bower's theory an improvement on Beck's theory, for several reasons: its clearly testable predictions; its acknowledgement that negative thinking can be an antecedent, as well as a consequence of depressed affect; its view of depression as an extreme form of the normal effect of mood on information processing, which thus provides an alternative view of cognitive vulnerability without having to evoke the matching of trigger events with dysfunctinal assumptions and schemata; and its ability to explain the maintenance of depression. In short, he considers Bower's theory more scientifically sound than Beck's. However, Teasdale (1993) and Teasdale and Barnard (1993) criticize Bower's theory on several counts and have put forward an alternative theory, the Interacting Cognitive Subsystems (ICS) framework which will be described briefly because of its potential influence on cognitive therapy.

ICS aims to bring to clinical psychology insights derived from cognitive science. Teasdale (1993) considers that Beck's model depends on lay concepts of cognition where cognitions refer only to consciously experienced thoughts and images and schemata to beliefs and assumptions. He considers that research studies and clinical observations have higlighted certain problems with cognitive therapy: cognitive therapy is not uniquely more effective than other psychological treatments (e.g., behavior therapy, Gallagher & Thompson, 1982; Interpersonal Psychotherapy, Elkin et al., 1989); antidepressant medication reduces negative thinking to the same extent as cognitive therapy (Simons et al., 1984); there is no evidence of dysfunctional assumptions in remitted patients (Blackburn et al., 1990); in therapy, it sometimes appears that patients can experience emotional reactions without identifiable negative automatic thoughts; rational argument in therapy often appears ineffective in changing emotional responses; and for more refractory problems, for example, personality disorders, noncognitive methods of treatment have had to be borrowed from other schools of therapy, for example, Gestalt therapy (Beck, Freeman et al., 1990).

On the other hand, Bower's (1981) model, according to Teasdale (1993), fails because of the lack of differentiation in the semantic networks which are described. These appear to represent knowledge in a single format, so that specific concepts and the relationship between them is not differentiated. Higher order of meaning is not explained and, therefore, no distinction can be made between "hot" cognitions which are associated with a high level of emotion and "cold" cognitions which are reported at an intellectual level, without accompanying emotions.

Teasdale and Barnard (1993) describe ICS as an information processing model which attempts to take into account *all* aspects of information processing, and thus, probably succeed in developing in more detail Ingram and Kendall's (1988) model described earlier. They postulate nine types of information, encoded in separate mental codes, representing different aspects of experience; for example, sensory experience (sensory and proprioceptive codes); regularities in the sensory code patterns (intermediate structural description codes); specific and generic levels of meaning (meaning codes); and information required for effector action (effector codes). Each type of information is processed by its own specialized subsystem and encoded in separate memory stores. Information processing involves the transfer of information between subsystems and its transformation from one mental code to another.

Importantly for cognitive therapy, in the "meaning codes" two different codes are described relating to two highly different levels of meaning. The propositional code encodes specific meanings, discrete concepts, and the relationship between them. This is akin to Bower's semantic network, for example, "my neighbour is gray haired." The implicational code encodes generic, holistic levels of meaning which are difficult to convey in language: it relates to recurring very high order regularities across all information codes. Only this level of meaning is linked directly to emotion, with implicit meaning content, for example, "something wrong." Implicational meaning has a high level of abstraction; is influenced by contextual sensory features, for example, facial expression, tone of voice, bodily arousal; and represents generic features of experience which cannot be expressed in single sentences. The implicational code represents schematic models of experience with which mood biases are associated. Thus, depression is associated with the regeneration of depression-related schematic models when there is a shift in the prevailing high-order mental models of self and world which dominate information processing. This shift in the interrelationship between high order mental codes, not the activation of a particular cognitive node, leads to a negative content of thought in the form of negative attributions, evaluations, and memories.

Although this model appears at times overly complex and abstract, the clear differentiation between propositional and implicational levels of meaning is useful to understand the process of therapy and to make sense of failures and successes in therapy. The central goal of therapy is evidently to change implicational meaning related to depressive or anxious schematic models by substituting alternative patterns of meaning related to more adaptive schematic models. Since this abstract, generic level of meaning is made up of various elements, such as specific meanings, bodily state, and sensory information, such as tone and volume of voice and visual information, changes in any of the elements may bring therapeutic change. Therapy would thus involve different elements: change in meanings and/or change in sensory input, adding new elements to an experience through guided imagery, and paying greater attention to feelings through the use of emotional methods of treatment as used in Gestalt therapy. Interestingly, such therapeutic approaches have been adopted in cognitive therapy, especially for personality disorders. It seems that clinicians inspired by clinical insight have reached the same point as cognitive theorists, although through a different route, and perhaps without a proper rationale to explain their methods of treatment.

6.03.2.6 Other Cognitive Approaches

Beck's theories in the original form, and as further developed through research and clinical experience, have been the main emphasis in the previous sections because it is the approach which has led most clearly to specific methods of treatment which have been tested widely in controlled outcome studies. However, some other approaches have also been influential, in particular Ellis' RET, Meichenbaum's self-instructional training, and clinical developments of Seligman's learned helplessness theory by Abramson and her colleagues in the hopelessness theory of depression. These will be described briefly in this section.

6.03.2.6.1 Rational-emotive therapy

Ellis (1989) describes himself as the first major cognitive-behavioral therapist in view of his writings and practice dating back to 1957

(Ellis, 1957, 1962). RET, now relabeled REBT (rational-emotive-behavioral therapy), is based on an "ABC" theory of psychopathology, stating that activating events (A) do not directly cause emotional and behavioral consequences (C), but that the mediating variable of beliefs (B) about these events exercises the major influence on feelings and behavior. As such, the theory is quite close to Beck's, but the emphasis is clearly on beliefs only, as opposed to different aspects of cognition, for example, the content, form, and structure of thought. The therapeutic thrust of RET has, therefore, been on irrational beliefs as the cause of emotional problems. Rational beliefs are defined as those promoting survival and happiness and as likely to find empirical support in the environment, in contrast with irrational beliefs which are unlikely to find empirical support and reflect "musts" and "should." Rational beliefs will lead to appropriate negative emotions (sorrow, annoyance, regret) in the face of losses or difficulties, whereas irrational beliefs will lead to inappropriate negative emotion (depression, extreme anger, guilt). Haaga and Davison (1993) argue that the definition of rationality and irrationality is problematic in that irrationality is not the prerogative of emotionally disturbed individuals. Extensive research has shown that much of the thinking of nondisturbed people is irrational (Alloy & Abramson, 1979; Taylor & Brown, 1988). Irrational beliefs in RET are often defined by lists of typical beliefs which are often encountered in clinical practice (Ellis, 1962), for example:

(i) there is a dire necessity to be loved for everything one does;

(ii) certain acts are awful and wicked and people should be punished who perform such acts;

(iii) it is horrible when things are not the way one would like them;

(iv) human misery is externally caused and is forced on one by outside people and events;

(v) if something is or may be dangerous, one should be terribly upset about it;

(vi) it is easier to avoid than face life's difficulties and self-responsibilities;

(vii) one needs something other or stronger or greater than oneself on which to rely;

(viii) one should be thoroughly competent, intelligent, and achieving in all possible aspects;

(ix) because something once strongly affected one's life, it should indefinitely affect it;

(x) one must have certain and perfect control over things;

(xi) human happiness can be achieved by inertia and inaction; and

(xii) one has no control over one's emotions and one cannot help feeling certain things.

Such beliefs have been described in lists of a dozen to lists of several hundreds specific ones, to a few general categories with many exemplars (Ellis & Bernard, 1985). Specific questionnaires to measure irrational beliefs, such as the Rational Belief Inventory (Shorkey & Whiteman, 1977) and the Irrational Beliefs Test (Jones, 1968) have been criticized for confounding irrational beliefs with negative emotions.

Ellis and Whiteley (1970) make a difference between "elegant" and "inelegant" RET techniques. Elegant or preferential RET involves forceful disputation of the patient's irrational beliefs with the aim of making profound philosophical changes in the patient. However, this approach is not suitable for all patients, for example, for those with limited intellectual resources or with poor motivation. In such cases other methods, as used in cognitive therapy, are acceptable. This is described as inelegant or general RET, involving manipulation of environmental circumstances, teaching coping strategies, and "persuading clients that their perceptions of events are incorrect" (Raitt, 1988, p. 202). Persuasion is, however, definitely not a Beckian method of cognitive therapy which advocates instead the use of inductive methods to guide patients to evaluate their cognitions and make their own discoveries. Ellis (1980), in his comparison of RET and cognitive behavior therapy, emphasizes the philosophical stance of RET which is that: (i) people create their own emotional disturbances through irrational, absolutistic beliefs; (ii) as people have free-will, they can choose to disturb themselves or not; (iii) to bring about change, active work at modifying thoughts, feelings, and behaviors is necessary; (iv) profound philosophical change will bring about modification in emotional and behavioral reactions; (v) long-range hedonism is more healthy than short-term hedonism; and (vi) a scientific outlook, rather than an unscientific religious or mystical outlook, is likely to bring greater emotional health and satisfaction.

He rightly says that such a philosophical stance is absent in cognitive behavioral therapy which emphasizes evaluation and modification of cognitive processes to bring about long-term symptomatic changes, instead of deep philosophical changes.

The efficacy of RET has been tested in a number of studies (Haaga & Davison, 1989; Kendall, 1984; Zettle & Hayes, 1980), with encouraging results. However, the studies have been highly criticized for their poor methodology, involving nonclinical samples, no follow-up evaluation, poor outcome measures, no attempt at measuring treatment adherence, and the lack of differentiation between the two versions of RET (Haaga & Davison, 1993).

6.03.2.6.2 Self-instructional training

Self-instructional training (SIT) is the therapeutic method described by Meichenbaum (1977) in cognitive-behavior modification (CBM). As the term indicates, CBM was a development of behavior therapy and behavior modification at the time when efforts were being made to incorporate cognition as a valid variable in behavior therapy (Mahoney, 1974), because of the growing dissatisfaction with the empirical and theoretical basis of radical behaviorism. Cognitive-behavior therapists proposed that cognitions could be viewed as covert behaviors, subject to the same laws of learning as overt behaviors. Homme (1965) coined the term "coverants" to denote cognitions as covert operants, in Skinner's language, which are responsive to both external and internal contingencies and altered by contiguous pairings, through covert sensitization (Cautela, 1973). Meichenbaum (1993) describes the process as "client's self-statements and images were viewed as discriminative stimuli and as conditioned responses that come to guide and control overt behavior" (p. 202). Following from that, SIT aimed to decondition maladaptive patterns of behavior by training in self-talk which would establish and strengthen new patterns of behavior and by rehearsing adaptive coping skills. "The technology of behavior therapy, such as modelling, mental rehearsal, and contingency manipulations, was used to alter not only clients' overt behaviors, but also their thoughts and feelings" (p. 202) (Meichenbaum, 1993).

Meichenbaum (1977) describes the application of SIT and successful outcomes in hyperactive and impulsive children, socially withdrawn children, adult schizophrenics, and in creativity training. An example of SIT with impulsive children involves the following steps:

(i) an adult performs the task while talking to himself out loud (cognitive modeling);

(ii) the child performs the same task under the direction of the model's instructions (overt, external guidance);

(iii) the child performs the task while instructing himself or herself aloud (overt self-guidance);

(iv) the child whispers to himself while he or she goes through the task (faded, overt self-guidance);

(v) finally, the child performs the task while guiding his or her performance via private speech (covert self-instruction).

Over a number of training sessions, the package of self-statements modeled by the experimenter and rehearsed by the child is enlarged by the means of response chaining and successive approximation procedures. The skills which are taught through modeling are: problem definition, focusing attention and response guidance, self-reinforcement, self-evaluative coping skills, and error correcting options (I'm doing okay ... if I make a mistake, I can correct it and go on more slowly). The same operant conditioning principles of chaining and shaping were used over a number of training sessions to teach schizophrenic patients to use complex sets of self-statements.

The modification of self-talk or of automatic thoughts is central to cognitive therapy of the emotional disorders in adults, but the specific techniques of SIT appear particularly useful for patients with less well-developed verbal skills, for example, children, adults with learning difficulties, and severely impaired individuals such as schizophrenic patients. It has also been shown to be effective as a version of cognitive-behavioral therapy with phobic and anxious patients (Chambless & Gillis, 1993).

6.03.2.6.3 Hopelessness theory of depression

Seligman's theory of learned helplessness (Seligman, 1975; Seligman & Maier, 1967), as a model of depression derived from animal experiments where uncontrollable shocks were administered, was criticized for not being an adequate model for depression in humans. The model did not appear to reflect the complexity of human depression and the varied presentation of depression. As a result, a reformulated learned helplessness model was proposed by Abramson, Seligman, and Teasdale (1978), based on attributional theory, which described a particular type of depression, namely hopelessness depression. In brief, the theory stated that when an individual makes causal attributions which are internal, global, and stable for negative events, but which are external, specific, and unstable for positive events, expectations are created that highly desired outcomes are unlikely to occur or that highly aversive outcomes are likely to occur and that the individual has no available response to change the likelihood of occurrence of these outcomes. These expectations and the occurrence of a negative event were seen as a sufficient proximal cause of depression. However, Abramson et al. (1978) were aware of problems in this analysis, in that not all highly improbable, but highly desired outcomes, will be a sufficient cause of depression. For example, it may be desirable to win several million dollars on the weekly lottery, but people do not generally become depressed if they fail to win. There are other characteristics of the desired outcomes, for example, how much concern exists about them and how possible they are, which may determine whether their nonoccurrence is a sufficient proximal cause of depression.

Abramson, Alloy, and Metalsky (1988) have clarified and revised the helplessness theory of depression. They describe it as a diathesis stress model, relevant to one hypothesized subtype of depression. The hopelessness theory specifies not only a proximal sufficient cause, but also potential distal causes. A negative life event is interpreted by an individual who has a depressogenic attributional style (the diathesis) as due to stable, internal, global factors and high importance is attached to the event. These attributions may be modulated by situational cues (consequences, consistency of occurrence, and distinctiveness). The depressogenic attributions lead to lowered self-esteem and to feelings of hopelessness (which can be increased by social factors, for example, lack of social support) which are seen as sufficient to lead to hopelessness depression. Hopelessness depression is characterized by retarded initiation of voluntary responses (motivation symptom), difficulty in seeing that similar or related outcomes can be controlled (cognitive symptom), and sad affect (emotion symptom). Although the specification of a subtype of depression as hopelessness depression in reaction to negative situations has not led to specific methods of treatment, the theory helps to give a cognitive rationale for the well established finding of the role of life events in depression (Brown & Harris, 1978). It also pinpoints the thinking style which may be of particular importance in situational depression, and which should, therefore, be targeted in cognitive therapy.

6.03.3 APPLICATION OF COGNITIVE THERAPY

6.03.3.1 General Principles of Cognitive Therapy

There are several textbooks which describe cognitive therapy methods in detail for various psychiatric disorders: for depression (Beck et al., 1979; Blackburn & Davidson, 1995; Williams, 1992); for anxiety (Beck, Emery, & Greenberg, 1985; Blackburn & Davidson, 1995); for personality disorders (Beck, Freeman et al., 1990; Layden, Newman, Freeman, & Morse, 1993; Linehan, 1993; Young, 1990); for groups of disorders (Beck, 1995; Blackburn, Twaddle et al., 1996; Dobson, 1995; Hawton, Salkovskis, Kirk, & Clark, 1989; Padesky & Greenberger, 1995); for psychosis (Birchwood & Tarrier, 1994; Fowler, Garrety, & Kuiper, 1995; Kingdon & Turkington, 1994); for substance abuse (Beck, Wright, Newman, & Liese, 1993); for bipolar disorder (Basco & Rush, 1996); and for inpatients (Wright, Thase, Beck, & Gudgate, 1993). In this chapter, the general characteristics of cognitive therapy are described and attention is focused on developments which have evolved following the theoretical developments described above.

Cognitive therapy was first developed as a short-term treatment of 12–16 weeks, for unipolar depressed outpatients (Beck et al., 1979). The extension of its application to an ever increasing range of conditions and of disorders may be a cause for concern for some, but need not be surprising in view of the fact that cognitive theory is meant to be a comprehensive theory of psychopathology. For each disorder, the underlying generic model is applied, with additional components specific to each disorder (see later chapters on specific disorders). Newer applications have not been tested in controlled outcome studies, but the empirical basis of cognitive therapy remains very much the tradition, with models tested in experimental studies, followed by case studies, and then by controlled trials.

For most disorders cognitive therapy remains short-term, except in the case of personality disorders when therapy can extend to one or two years. Whereas in short-term cognitive therapy, weekly one-hour sessions are the norm, in personality disorders therapy sessions are often more infrequent, allowing the patient more time for homework assignments and more time to get over the high levels of emotion which may be stirred up during therapy. Typically, short-term therapy may last 10–20 sessions, although in some cases (especially in panic disorder) fewer sessions may suffice. Sessions are structured by the use of an agenda which is set collaboratively by the patient and the therapist. This ensures the active participation of the patient and the appropriate use of time. Generally, a session agenda will include a review of previous assigned homework; setting up one or two relevant areas for discussion, these being often related to previous homework; session feedback and deciding on appropriate homework for the coming week. Throughout therapy, the therapist must ensure that the process is collaborative, by giving and asking for feedback, by rehearsing, and by questioning. The therapist remains active and directive, but never prescriptive. The style is gentle and questioning, guiding the patient to elucidate their emotions and thoughts, to evaluate them, and to arrive at alternative interpretations and solutions. This style of questioning has been described as socratic questioning (Overholser, 1993a, 1993b). Questions are used for gathering information, for discovering new perspectives, for finding commonalities between situations, patterns of thinking and emotions (synthesis), and for achieving change. Overholser (1993a) differentiates between seven types of socratic questions: (i) memory questions (When did the problem first begin? When did it last happen? What did you do when it happened?); (ii) translation questions (What does it mean to you? How can we make sense of this?); (iii) interpretation questions (How are these situations similar? Do your problems at work seem similar in any way to your problems at home?); (iv) application questions (What have you tried in order to solve this problem? How will you go about making these changes?); (v) analysis questions (What evidence do you have for this? How could you tell if you are right or wrong?); (vi) synthesis questions (In what other ways could you look at this situation? What does all this say to you? What does it mean to you to be a mother?); and (vii) evaluation questions (What does it mean to you to be a success? How do you rate yourself as a person?).

Another general characteristic of cognitive therapy is openness, that is, the therapist is explicit about the model of therapy, about the rationale for the procedures which are used, about the formulation of problems, about their own reaction in the therapeutic relationship, and about the rationale for homework assignments. Feedback is elicited not only regarding the content of therapy, but also about the patient's reaction to the therapist. This explicit and open style not only fosters collaboration, the model being of two scientists working together to solve problems, but also ensures that therapist and patient share a common understanding of what is going on in therapy. It is particularly important at the onset of therapy to explain the model of therapy by sharing the generic model of cognitive therapy with the patient, using the diagram shown in Figure 4, with real examples from the information gathered in the first assessment.

Therapy is problem oriented: therapist and patient engage in a functional analysis of problems in the assessment stage, so that therapy remains focused. The functional analysis includes symptoms (panic attacks, mood, hopelessness, suicidal wishes or behaviors, situational avoidance, etc.), problem situations (work, marital relationship, interpersonal relationship, etc.), life condition (employment, social support, social network, etc.), proximal trigger situations (e.g., loss or threat situations), maintaining factors (current hassles and problems, coping strategies), distal factors (short developmental history), typical automatic thoughts, and typical behaviors. This analysis leads to an agreed list of problems which can be prioritized and targeted for therapy. An example of assessment is given in Figure 5.

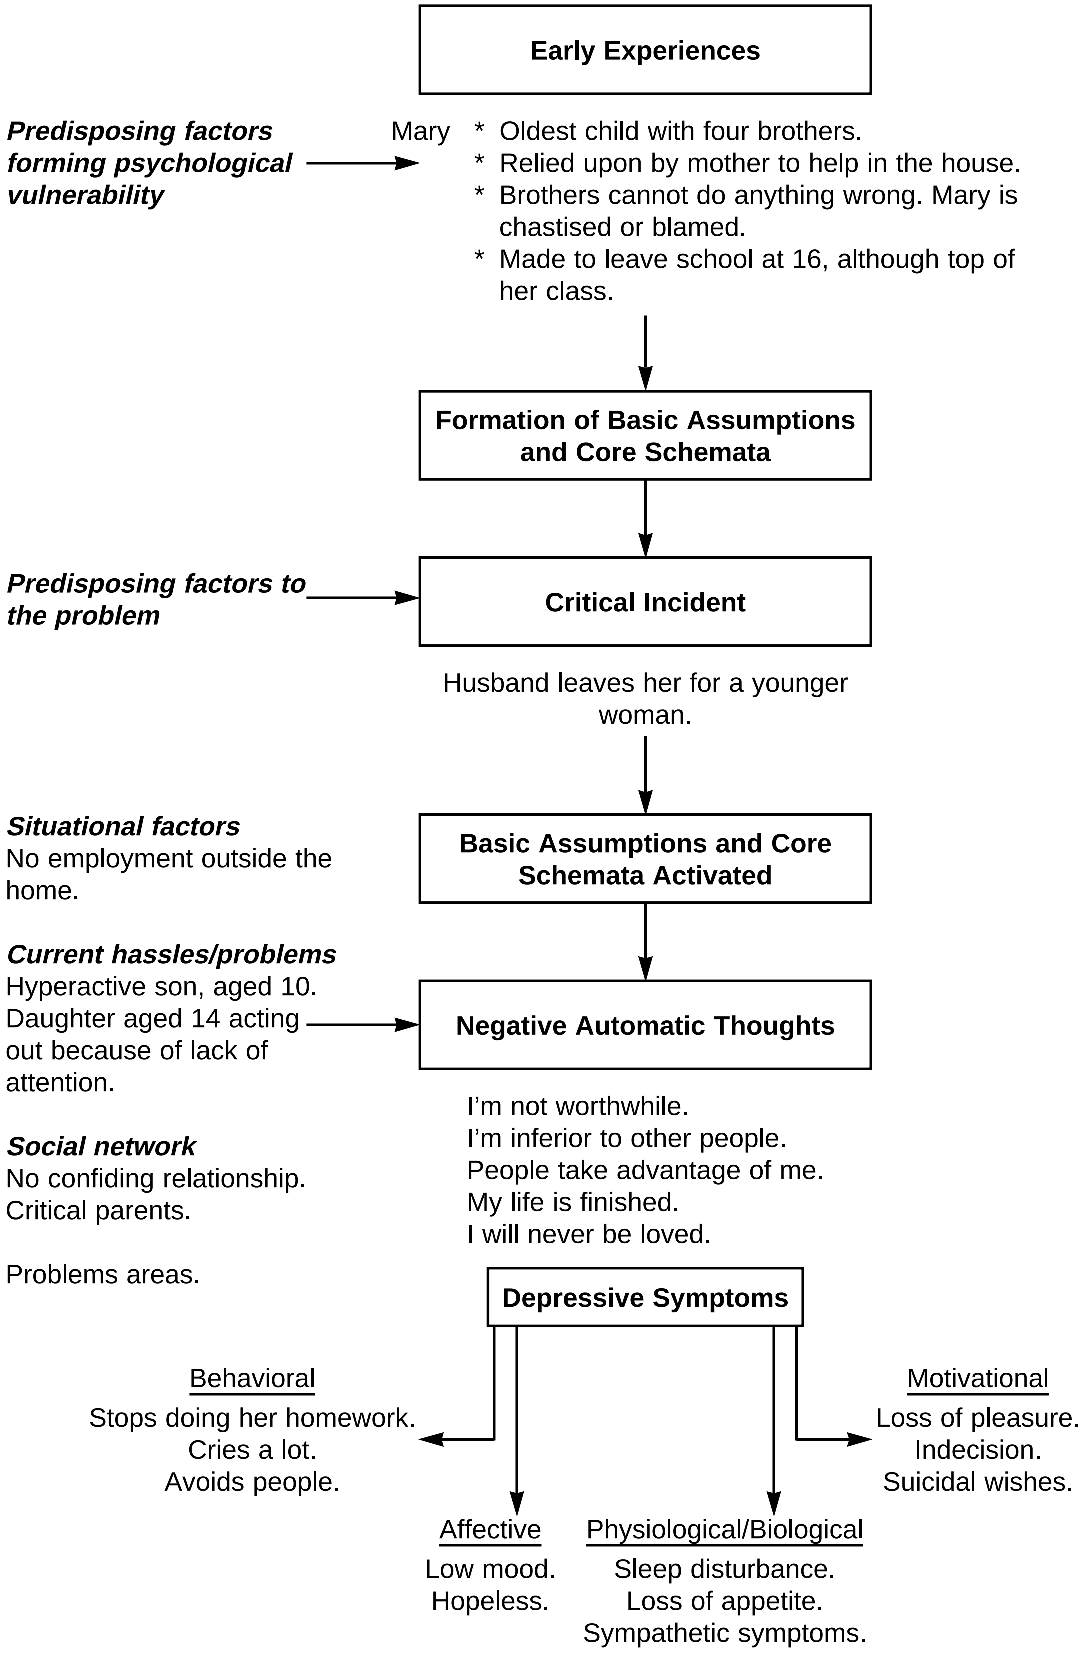
Figure 5 indicates that although a detailed conceptualization, as shown in Figure 2, cannot be made at the assessment stage of therapy, nonetheless the therapist may already have some clues about the basic assumptions and the core schemata of the patient derived from the themes of the negative automatic thoughts and from the pattern of hypothesized predisposing factors from early childhood experiences. In the example, a basic assumption may be "If people do not treat me properly, this means I am worthless" and a core schema may be "I am worthless." Through questioning (e.g., What do you think is the most pressing problem for us to work on? What would help you most at the moment?), problems are prioritized to bring about effective change quickly. This is a two-way process, so that the therapist and the patient reach conclusions collaboratively about what priorities suggest themselves. In the case described in Figure 5, the suicidal ideas and wishes of the patient would take priority and it is usual to work then at a symptom level, using behavioral methods of treatment to increase activity, in particular pleasurable activities. However, concurrently, during the therapy sessions, the therapist would start socializing the patient into cognitive methods of treatment to increase awareness of automatic thoughts, and to begin to evaluate these thoughts. An initial conceptualization can then follow at about the fifth or sixth session of therapy, which is shared with the patient.

Conceptualization is an aspect of cognitive therapy which is more emphasized now than it used to be in the early days of cognitive therapy (Blackburn et al., 1996; Persons, 1989; see Chapter 6.02, this volume for a detailed discussion). An example of a conceptualization was given in Figure 2 above. The cognitive conceptualization of cases will vary from disorder to disorder and is done within the specific cognitive theory framework of that disorder. For example, a conceptualization of a case of panic disorder is given in Figure 6 to highlight the difference from the case of depression in Figure 2.

As Persons (1989) points out, conceptualization plays a crucial role in cognitive therapy:

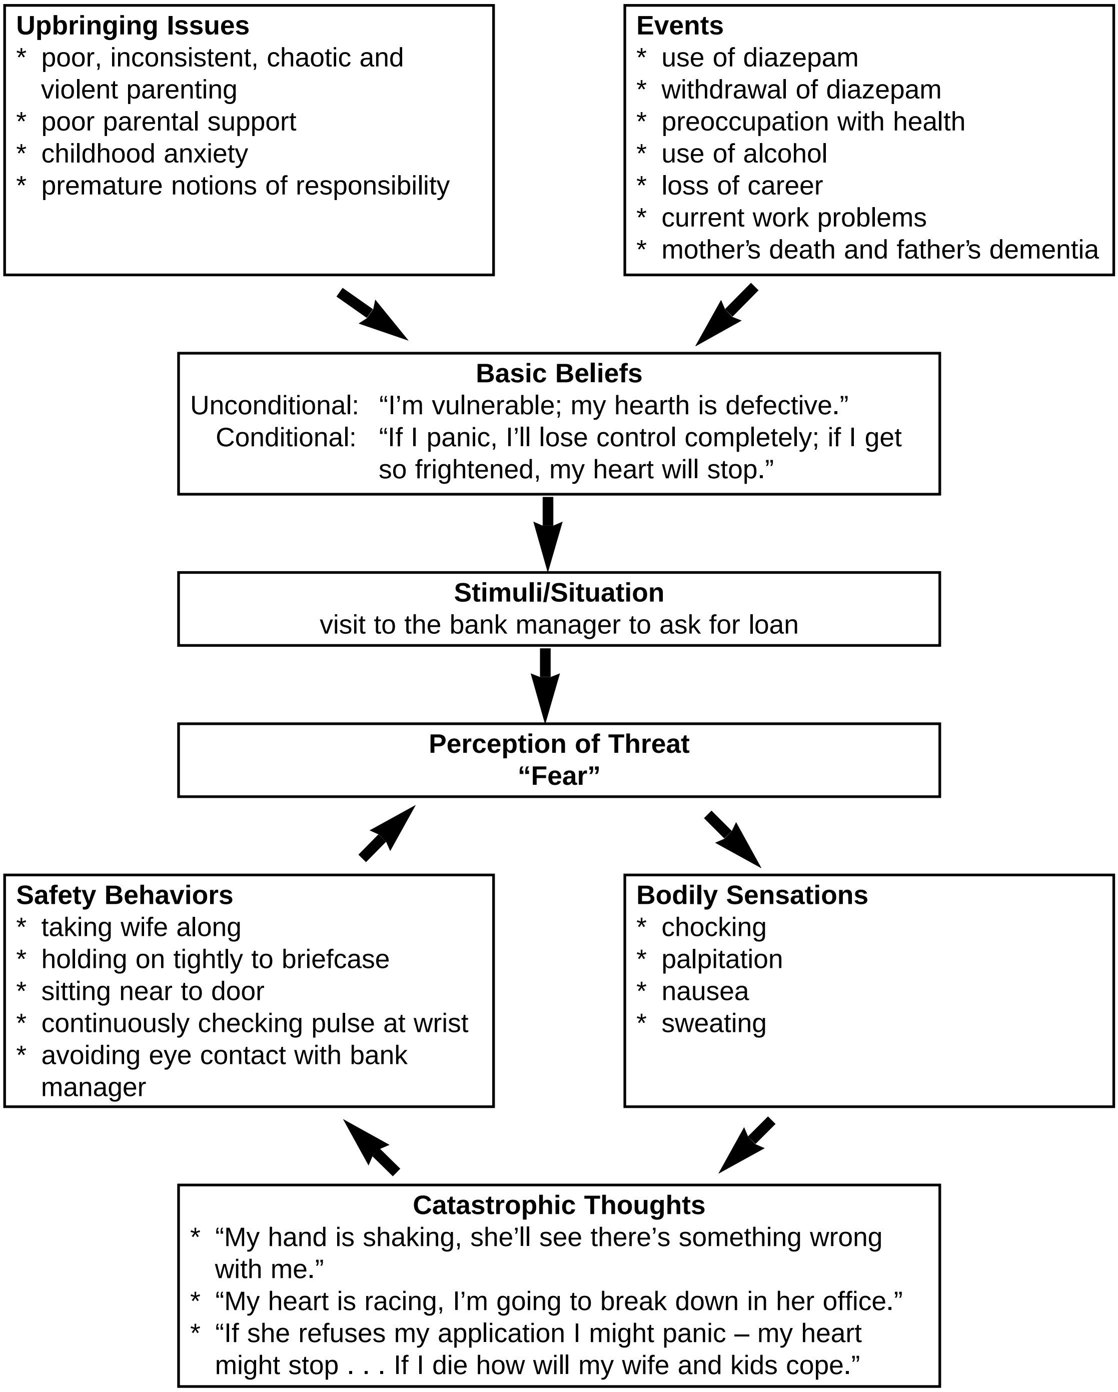
(i) It helps the therapist to choose an intervention strategy, for example, it might indicate that environmental changes are possible and indicated or that the patient's view of themself as vulnerable and weak is more central than their avoidance behaviors.

(ii) It helps to choose the treatment modality, couple therapy instead of individual therapy.



Early Experiences
Predisposing factors forming psychological vulnerability
Mary
* Oldest child with four brothers.
* Relied upon by mother to help in the house.
* Brothers cannot do anything wrong. Mary is chastised or blamed.
* Made to leave school at 16, although top of her class.
Formation of Basic Assumptions and Core Schemata
Predisposing factors to the problem
Critical Incident
Husband leaves her for a younger woman.
Situational factors
No employment outside the home.
Current hassles/problems
Hyperactive son, aged 10.
Daughter aged 14 acting out because of lack of attention.
Social network
No confiding relationship.
Critical parents.
Problems areas.
Basic Assumptions and Core Schemata Activated
Negative Automatic Thoughts
I'm not worthwhile.
I'm inferior to other people.
People take advantage of me.
My life is finished.
I will never be loved.
Depressive Symptoms
Behavioral
Stops doing her homework.
Cries a lot.
Avoids people.
Motivational
Loss of pleasure.
Indecision.
Suicidal wishes.
Affective
Low mood.
Hopeless.
Physiological/Biological
Sleep disturbance.
Loss of appetite.
Sympathetic symptoms.

Figure 5 Examples of a functional analysis of a problem at assessment (Mary, age 42).



Upbringing Issues
* poor, inconsistent, chaotic and violent parenting
* poor parental support
* childhood anxiety
* premature notions of responsibility
Events
* use of diazepam
* withdrawal of diazepam
* preoccupation with health
* use of alcohol
* loss of career
* current work problems
* mother's death and father's dementia
Basic Beliefs
Unconditional: "I'm vulnerable; my hearth is defective."
Conditional: "If I panic, I'll lose control completely; if I get so frightened, my heart will stop."
Stimuli/Situation
visit to the bank manager to ask for loan
Perception of Threat
"Fear"
Safety Behaviors
* taking wife along
* holding on tightly to briefcase
* sitting near to door
* continuously checking pulse at wrist
* avoiding eye contact with bank manager
Bodily Sensations
* chocking
* palpitation
* nausea
* sweating
Catastrophic Thoughts
* "My hand is shaking, she'll see there's something wrong with me."
* "My heart is racing, I'm going to break down in her office."
* "If she refuses my application I might panic – my heart might stop . . . If I die how will my wife and kids cope."

Figure 6 Conceptualization of a panic disorder case (reproduced by permission of Souvenir Press from *Cognitive therapy in action. A practitioner's case-book*. Blackburn, Twaddle et al., 1996).

(iii) It guides the therapist in the choice of an intervention point, for example, what changes are likely to bring about the most gain and are likely to have the biggest impact on the hypothesized basic assumptions and schemata.

(iv) It helps the therapist to predict the patient's behavior, for example, is the patient likely to become over-dependent on the therapist or likely to be noncompliant in terms of attendance and homework assignments?

(v) It helps to make sense of the patient's relationship difficulties both in and out of therapy and this guides the therapist's behaviors.

(vi) It may help to understand why therapy is not working. The formulation may be wrong and the therapist needs to consider new information that might have transpired in the course of therapy and revise the original formulation of the patient's problems.

(vii) Because a good formulation should lead to appropriate strategies, methods of treatment, and intervention points, length of treatment can be much reduced as time is used effectively and economically.

6.03.3.2 Treatment Methods

Treatment strategies in cognitive therapy are driven by the case conceptualization which is itself firmly based in the cognitive theory of the emotions, as described in the earlier part of this chapter. Different targets of therapy may require a different balance of cognitive, behavioral, and emotional therapeutic methods, which emphasizes that cognitive therapy is not a series of techniques to be mastered and applied technically. It is a system of psychotherapy requiring a thorough understanding of the cognitive theory of the emotional disorders, familiarity with the experimental literature on which it is based, and knowledge and experience of psychiatric syndromes in general. In addition, the competent cognitive therapist needs to display the general qualities of a good psychotherapist; namely, genuineness, warmth, empathy, and understanding.

6.03.3.2.1 Behavioral methods

Behavioral methods of treatment typically are applied early on in therapy as they can often provide relief for distressing symptoms which may prevent therapy from progressing. It is also perhaps easier for patients to master behavioral techniques, while concurrently getting socialized in cognitive techniques. Behavioral techniques are not used in cognitive therapy without examining concomitant effects on cognitions and emotions.

Typical behavioral methods of treatment and the problems for which they are suitable are listed below:

(i) *Inactivity*. Scheduling of graded activities with reasonable goals to approximate in the long run the patient's normal routine.

(ii) *Indecivesiveness*. Planning daily activities and rescheduling activities for another day if the original plan has not been adhered to because of unforeseen circumstances. For life decisions, a more cognitive approach may be indicated (illustrated in Table 1).

(iii) *Procrastination*. Establishing detailed daily plans of activities to reduce decision making. Again, it is necessary to ensure that the plans are feasible and attainable.

(iv) *Lack of pleasure*. Scheduling of potentially pleasurable activities and rating activities for pleasure. The therapist needs to ensure that the patient is not showing an all or none response, that is not rating activities as pleasurable or not pleasurable and not confusing ratings of pleasure with ratings of achievement

(v) *Lack of concentration*. Practice engaging in activities (e.g., reading) in small bursts which are reinforcing, instead of persevering when concentration has gone or giving up altogether. The therapist must watch out for the patient's self-talk or automatic thoughts.

(vi) *Low mood*. Engaging in distracting and pleasurable activities. Mental imagery of pleasant memories.

(vii) *Anxious mood*. Distraction, relaxation techniques. Distraction techniques may involve focusing on an object and describing it in minute details; developing sensory awareness by concentration on visual, auditory, olfactory, and bodily sensations; mental exercises, for example, reading, watching a film, or doing the crosswords.

Relaxation is an important technique for patients who feel they have no control over how they feel. Several relaxation methods have been described (Bernstein & Borkovec, 1973; Goldfried & Davison, 1976), however, the applied relaxation method described by Ost (1987) has been shown to be particularly effective. It involves eight stages which can be taught sequentially or in subsets: giving a rationale for relaxation training; recognizing the early signs of anxiety; progressive relaxation; relaxation exercises without tensing the muscles first; cue-controlled relaxation, that is, inhaling and relaxing to the cue word relax; differential relaxation, that is, learning to relax while engaged in everyday activities; rapid relaxation by using several cues in the patient's environment; and, finally, application training which involves applying the learnt relaxation in anxiety provoking situations.

(viii) *Lack of motivation*. Schedule activities and grade for mastery and pleasure. The underlying rationale here is that the main problem lies in starting an activity and that, once started, motivation increases through the desire to finish the task (Zeigarnik, 1927) and the unexpected pleasure experienced, much as appetite may actually be stimulated by the act of eating, although there might not have been much desire to eat at the outset.

(ix) *Panic attacks*. Respiratory control exercises which reduce panic symptoms due to hyperventilation (Clark, 1989). The exercises consist in pacing breathing to 12 breaths per minute or eight breaths per minute by breathing for two seconds "in" and for two seconds "out"

(12 breaths/min) or three seconds "in" and three seconds "out" (eight breaths/min)

(x) *Avoidance*. Exposure to avoided situations, in a graded and repeated fashion, for example, social, phobic, or agoraphobic situations.

(xi) *Safety behaviors*. These are behaviors that anxious patients engage in when anxiety or panic feelings have already started, for example, holding on to solid objects, sitting down, pressing their head, checking their pulse rate. These behaviors can be very subtle and need to be elicited carefully or observed during a behavioral test. They need to be eliminated gradually as they maintain the patient's beliefs that symptoms are dangerous.

(xii) *Rituals*. Deliberate exposure to previously avoided situations or feared stimuli (including thoughts) and prevention of compulsive rituals and neutralizing behaviors, including neutralizing thoughts.

(xiii) *Problem situations*. Rehearsal in role-plays, with the therapist, of coping techniques and strategies, for example, assertiveness training, negotiations with a spouse or at work, and anger control.

It is already evident from the list of behavioral methods described above that they are applied within a general cognitive strategy to help in identifying the cognitions which are related to the problems, to test the patient's predictions and to modify expectations about the self, the world, and the future.

6.03.3.2.2 Cognitive methods

(i) Identifying automatic thoughts

The main emphasis at the beginning of therapy, even while applying behavioral methods of treatment, is the patient's automatic thoughts, which are considered as the basic data of cognitive therapy. The patient needs to understand the nature of automatic thoughts and how they affect emotions and behaviors and this is done from the time of assessment, through questioning, noting spontaneous reports of examples of automatic thoughts, and including them in the model of therapy which is presented to the patient. Because the very nature of automatic thoughts indicates that they are habitual and involuntary, some patients have difficulty in getting access to their "hot" automatic thoughts for several reasons: they have been used to taking them for granted; or they report a commentary about their automatic thoughts (thoughts about thoughts) through excessive intellectualization; or they feel embarrassed about their automatic thoughts; or they consider them as silly. A great deal of socialization is, therefore, necessary to guide the patient early on in therapy. A good way for the therapist to decide whether they have accessed the right automatic thought is to ask themself: "Is this thought consistent with the emotion that is reported?", "Is this thought consistent with the degree of emotion that is reported?", and "If I had the same thought, would I feel as bad?"

There are several methods to guide the therapist about how to access the patient's automatic thoughts:

(a) Direct questions. "What was going through your mind when you felt panicky?"; "What went through your mind when your husband criticized your housework?" This is evidently the easiest method and it is surprising how often this is enough to trigger the appropriate negative automatic thoughts. This questioning also serves as a model for the patient to tap into their automatic thoughts at the time of strong emotions or of self-defeating behaviors.

(b) If direct questions do not prove useful, the therapist poses a series of questions to guide the patient to access the automatic thoughts. This approach has been labeled "guided discovery" or "socratic questioning." It is the main technique which cognitive therapists need to master. It demands good listening skills, an understanding of the patient's style of thinking and a formulation of the problems which acts as a guide or a map.

(c) Sometimes the patient describes situations or events which may have caused problems in a detached way, the way they may describe a film or a book or a road accident that one might have witnessed. These are probably examples of propositional and not implicational meaning, as described by Teasdale (1993). In such cases, the therapist can use mental imagery to help the patient relive the actual situation as vividly as possible, with all the sensory input which might be involved. This method helps in triggering strong emotions and the accompanying automatic processing which might have taken place.

(d) For interpersonal situations, role-plays serve the same purpose. Having elicited the details of what actually took place, the therapist reenacts the situation by playing the role of the other person involved as realistically as possible, using posture, tone, and volume of voice to trigger the emotions and, hence, the automatic thoughts.

(e) Moments of strong emotions are, therefore, of crucial importance to access automatic thoughts. If emotion is not shown or expressed in therapy, the therapist tries to elicit emotions through imagery or role plays. If it is present during the session, the therapist uses the

Table 1 A method for dealing with indecisiveness. A married woman, with two school age children, having recovered from a depressive illness, cannot decide about her future plans.

Alternatives	*Pros*	*Importance*	*Cons*	*Importance*	*Balance*
1. Go back to the same job on a full-time basis	I enjoyed the job, because of its responsibility.	80	It was not a 9am-5pm job, so I never knew when I would get home and sometimes I had to take work home with me.	100	
	I knew the job and could do it well.	80	The pressure might make me ill again.	100	
	If I got depressed again I could have time off, as the employers were very understanding the last time.	100	It was not fair on the children not to spend more time with them.	100	
	It gave me a good income of my own and made me feel independent.	20			
		Σ + 280		Σ + 300	Σ − 20
2. Go back to the same job on a part-time basis.	It would give me more time with the children.	100	I would no longer have the responsibility which I enjoyed.	80	
	The part-time income would still make me feel independent.	20	It is a difficult job to do part-time. I might find myself doing as much as before for less money.	80	
	It would be less pressure and I might feel better.	100			
	I would be able to move to full-time again when the children grow up.	100			
		Σ + 320		Σ − 160	Σ + 160
3. Look for another part-time job which is less demanding	It would involve regular hours—more time at home.	100	Better the devil you know. A new job might turn out inappropriate.	80	
	May be less interesting, but would get out of the house nonetheless.	60	I get bored by routine jobs.	80	
	My husband would be happier with this.	50	Less money.	20	
	Less pressure would be better for my health.	100			
		Σ + 310		Σ − 180	Σ + 130
4. Not go back to work at all.	A lot of free time to do things with the children.	100	I would miss having an interesting job outside the home.	100	
	I could use the spare time at home to study a language or something else.	30	I would be bored.	50	
	I could spend more time on my hobbies: gardening, cooking, going out.	20	I would be resentful.	50	
	Both sets of parents and my husband would approve.	50	In nine years time, by the time children have grown up, I will be older and it would be more difficult to get into the job market.	20	
	May be better for my health.	100			
		Σ + 300		Σ − 220	Σ + 80

Final decision: There are advantages and disadvantages for all alternatives, but going back to the same job on a part-time basis is preferable.

Source: Blackburn, 1993, pp. 94–97.

moment to help the patient access the automatic thought. It is particularly important to be aware of emotions which may not appear to be related to the current subject of discussion: the patient may become fidgety or tense, blush or start crying and the therapist then asks "what"s going through your mind just now?"

(f) Behavioral tasks have already been described in the previous section as an invaluable method to train the patient to become aware of their thoughts as they feel the negative emotions aroused while encouraging in behavioral tests.

(g) At the beginning of therapy, patients can increase their awareness of negative thoughts by simply counting them, using some sort of counter which they keep with them at all times or keeping a tally on an index card.

(h) The classical method of increasing awareness of negative automatic thoughts is the use of Dysfunctional thoughts records (DTRs) where the patient records the situation (what was going on) when they felt a strong negative emotion, what the emotion was and at what intensity and what were the automatic thoughts and what was their degree of belief in their automatic thoughts. Only these three columns are used at the beginning of therapy and they should be used in the session for training, before being given as a homework assignment. Several examples of DTRs have been given in cognitive therapy textbooks (Blackburn & Davidson, 1995; Hawton et al., 1989).

(ii) Evaluating automatic thoughts

In the therapy sessions and as homework assignments, the patient learns to evaluate their automatic thoughts. This can probably be considered the core of cognitive therapy, involving the acquisition of the necessary skills to distance oneself from one's automatic processing of information and to treat the products of thoughts as interpretations of reality, rather than reality itself. These skills are of crucial importance as they are generalisable to the evaluation of others and to basic assumptions and core beliefs as well.

The evaluation of automatic thoughts is done through careful questioning to guide the patient to consider various alternatives to their original, automatic processing and to adopt more functional alternatives that they can test and come to believe in. The therapist's questioning becomes a model for the patient to apply to their thinking outside of therapy.

Questioning may take the form of:

(a) What is the evidence for this interpretation?

(b) Are there alternative interpretations which may be more realistic?

(c) What is the effect of thinking that on me, on others?

(d) What thinking errors am I making?

(e) Am I jumping to conclusions? (arbitrary inference),

(f) Have I considered all aspects of the situation (selective abstraction),

(g) Am I using one instance to draw general conclusions, when there is no basis to do this? (overgenalization),

(h) Am I catastrophizing? (minimization and maximization),

(i) Am I taking this personally when it may have nothing to do with me? (personalization),

(j) Am I thinking in black and white? (dichotomous thinking),

(k) Am I applying arbitrary rules, "shoulds" and "musts" when, in fact, there are no such rules?

Table 2 gives a list of 20 questions which can be given as a handout to patients to help them evaluate their automatic thoughts.

When the degree of belief in the original automatic thought is put in question, alternative interpretations can be considered, and the probability of these alternatives can be assessed. The alternative interpretation, after careful collaborative evaluation, can sometimes be seen clearly as more likely and more realistic, but even if this is not the case, when the alternatives are not more probable than the original interpretation, it is beneficial to see that one interpretation—is not necessarily correct, so that the degree of belief in the distressing interpretation becomes reduced.

In the process of revaluation, a negative event or outcome may be reattributed to external instead of internal, less global, and less stable causes (Abramson et al., 1978).

It is particularly important that the alternative interpretations or conclusions that are arrived at be owned by the patient, rather than dictated by the therapist, as the degree of belief in the alternatives will depend on that. Degree of belief in the alternatives are rated and the resultant emotions rated. Thus, it is not taken for granted that because alternatives have been considered, the patient would automatically believe in them and feel better. The DTR, with the five columns, Situation, Emotion, Automatic Thought, Alternative Response, and Outcome is used for that purpose. An example is given in Table 3.

To consolidate the patient's revaluation of their automatic thoughts and the degree of belief in them, several methods can be used, for example, rehearsal, role-plays, and behavioral tests. Rehearsal simply restates the same situation or equivalent situations and the typical automatic thoughts and the patient is invited to

Table 2 Twenty questions to help challenge negative thinking.

Question	*Response*
Am I confusing a thought with a fact?	The fact that you believe something to be true does not necessarily mean that it is. Would your thought be accepted as correct by other people? Would it stand up in court, or be dismissed as circumstantial? What objective evidence do you have to back it up, and to contradict it?
Am I jumping to conclusions?	This is the result of basing what you think on poor evidence. For instance, depressed people often believe that others are thinking critically about them. But none of us are mind-readers. How do you *know* what someone else is thinking? You may be right, but don't jump to conclusions—stick to what you know, and if you don't know, see if you can find out.
What alternatives are there?	Are you assuming your view of things is the only one possible? How would you have looked at this situation before you got depressed? How would another person look at it? How would you look at it if someone else described it to you?
What is the effect of thinking the way I do?	What do you want? What are your goals? Do you want to be happy and get the most out of life? Is the way you are thinking now helping you to achieve this? Or is it standing in the way of what you want?
What are the advantages and disadvantages of thinking this way?	Many distorted thought patterns do have some pay-off—that is what keeps them going. But do the disadvantages outweigh the advantages? If so, you can think out a new way of looking at things which will give you the advantages, but avoid the disadvantages of the old way.
Am I asking questions that have no answer?	Questions like "How can I undo the past?" "Why am I not different?" "What is the meaning of life?" "Why does this always happen to me?" "Why is life so unfair?" Brooding over questions like these is a guaranteed way to depress yourself. If you can turn them into answerable questions, so much the better. If not, don't waste time on them.
Am I thinking in black-and-white, all-or-nothing terms?	Nearly everything is relative. People, for instance, are not usually all good or all bad. They are a mixture of the two. Are you applying this kind of black-and-white thinking to yourself?
Am I using global words in my thinking?	Watch out for words like always/never, everyone/no-one, everything/nothing. The chances are that the situation is actually less clear-cut than that. Mostly it's the case of sometimes, some people, and some things.
Am I condemning myself as a total person on the basis of a single event?	Depressed people often take difficulties to mean that they have no value at all as a person. Are you making this kind of a blanket judgement?
Am I concentrating on my weaknesses and forgetting my strengths?	When people become depressed, they often overlook problems they handled successfully in the past and resources which would help them overcome current difficulties. Once they can change their thinking, they are often amazed at their ability to deal with problems. How have you coped with similar difficulties in the past?

Table 2 (continued)

Question	*Response*
Am I blaming myself for something which is not really my fault?	Depressed people, for instance blame themselves for being depressed. They put it down to lack of willpower, or weakness, and criticise themselves for not "pulling themselves together." In fact, scientists have been studying depression for many years and they are still not certain what causes it. Depression is a difficult problem to solve and blaming yourself for it will only make you more depressed.
Am I taking something personally which has little or nothing to do with me?	When things go wrong, depressed people often believe that in some way this is directed at them personally, or caused by them. In fact, it may have nothing to do with them.
Am I expecting myself to be perfect?	It is simply not possible to get everything right all the time. Depressed people often set unrealistically high standards for themselves. Then they condemn themselves for making mistakes, or acting in ways they would rather not have done. Accepting that you can't be perfect does not mean you have to give up trying to do things well. It means that you can learn from your difficulties and mistakes, instead of being upset and paralysed by them.
Am I using a double standard?	You may be expecting more of yourself than you would of another person. How would you react to someone else in your situation? Would you be so hard on them? You can afford to be as kind to yourself as you would be to someone else. It won't lead to collapse.
Am I paying attention only to the black side of things?	Are you, for instance, focusing on everything that has gone wrong during the day and forgetting or discounting things you have enjoyed or achieved?
Am I overestimating the chances of disaster?	Depressed people often believe that if things go at all wrong, disaster is sure to follow. If the day starts badly, it can only get worse. How likely is it that what you expect will really happen? Is there really nothing you can do to change the course of events?
Am I exaggerating the importance of events?	What difference does a particular event really make to your life? What will you make of it in a week, a year, 10 years? Will anyone else remember what you now see as a terrible thing to do? Will you? If you do, will you feel the same way about it? Probably not.
Am I worrying about the way things ought to be, instead of accepting and dealing with them as they are?	Are you allowing events in the world at large to feed your depression? Telling yourself life is unjust and people awful? It is sad that there is so much suffering in the world and you may decide to do what you can to change things, but getting depressed about it does nothing to help.
Am I assuming I can do nothing to change my situation?	Pessimism about the chances of changing things is central to depression. It makes you give up before you even start. You can't know that there is no solution to your problems until you try. Is the way you are thinking helping you to find answers, or is it making you turn down possible solutions without even giving them a go?
Am I predicting the future instead of experimenting with it?	The fact that you have acted in a certain way in the past does not mean to say that you have to do so in the future. If you predict the future, instead of trying something different, you are cutting yourself off from the chance of change. Change may be difficult, but it is not impossible.

Table 3 Example of automatic thoughts and how to answer them.

Situation	*Emotion* (rate degree, 0–100%)	*Automatic thoughts* (rate belief, 0–100%)	*Alternative responses* (rate belief, 0–100%)	*Outcome* (re rate belief automatic thought and emotion)
Woke up and kept thinking of office situation	Disturbed, anxious, low (70%)	What mess am I going to have to go to? (70%)	I'm crystal ball gazing. It may not be a mess. However, if it is less organized than before, it will be the responsibility of the supervisor. I can only do my work as well as I can and let other people worry about their work (100%)	Automatic thought (10%) Anxious (20%)

Source: Blackburn, 1993, p. 66.

evaluate these thoughts along the lines of the preceding discussion. In role plays, the therapist may reenact a typical distressful scenario and elicit thoughts and emotions or the therapist may play devil's advocate and play back the patient's automatic thoughts which they then have to modify using the skills which have been practiced beforehand. This is a particularly impactful method which usually triggers high emotional responses. Several attempts using role reversals are usually necessary. Finally, behavioral tests of the new interpretation can be devised collaboratively to check whether the new interpretation is indeed more probable. These may involve polling friends and relatives to check their opinions in reality rather than mind reading; facing rather than avoiding a confrontational or self-assertive situation to assess others' reactions; engaging in, say, panic provoking situations, making predictions, and reviewing the evidence after the behavioral test and drawing conclusions.

When dealing with automatic thoughts, several caveats need to be drawn to the attention of the therapist: working on peripheral rather than key automatic thoughts; dealing with questions instead of the underlying thought which prompts the question; buying into the patient's system instead of keeping to a questioning style; not engaging in a thorough evaluation of the thoughts; and not engaging in consolidation methods.

(iii) Basic assumptions and core schemata

These have been described in previous sections and are an integral part of the information processing model of the emotional disorders. It is considered that therapy would be incomplete without dealing with this aspect of the patient's cognitive system which underlies the way information is processed and which is considered to represent psychological vulnerabilities. Therapy at that level is therefore considered to be preventative. However, the relative emphasis put on eliciting and modifying core structures may vary from disorder to disorder, being most central in the personality disorders and in depression and general anxiety and possibly less so in obsessive-compulsive, panic, health anxiety, and psychotic disorders.

(iv) Determining basic assumptions and core schemata

As therapy progresses, general themes in problem situations and in automatic thoughts become evident, as are personal rules, and these are discussed with the patient within the conceptualization of problems as shown in Figures 2, 5, and 6.

The therapist listens attentively for the implicit meanings of the patient's statements and makes them explicit, as usual in question form, for example, "Does this mean that if people do not like you, you are no good?"; "Does this apply to everybody or only to some people?"; and "Does this mean that you are a failure?"

It is interesting to note that often, quite early on in therapy, the patient may express an automatic thought such as "I am a failure" which, in fact, is their core schema. At this stage, the patient may be totally unaware that this is their general view of themself and the therapist may have only an inkling that it is the patient's core schema. It is therefore advisable to treat the statement as an automatic thought at this stage, as the patient has not yet acquired the skills to evaluate automatic thoughts and an overall understanding of the common thread in all the problems has not yet been reached by the patient and/or the therapist.

To bring out the common themes in the automatic thoughts, the therapist can use several examples to extract the general implications of the automatic thoughts. This method has been labeled the "downward arrow" technique, where the automatic thoughts are accepted as possibly true and their ulterior catastrophic implications arrived at through questioning. An example is given in Table 4.

It is to be noted in the example illustrated in Table 4 that the patient is not encouraged to evaluate automatic thoughts at this stage, but instead is guided to consider the meaning implicit in the automatic thoughts which causes distress. At the end of this exercise, the therapist would help put the conclusion explicitly: "It seems from this that you are saying that people will not respect you if you do not do things perfectly? Is this right?" (basic assumption); "You also say that it would simply confirm the fact that you are worthless?" Other examples are then used to construct a consistent formulation which gives the patient an overall understanding.

It may be an aid to therapy to use standard questionnaires to elicit basic assumptions and core schema, for example, the DAS (Weissman & Beck, 1978) or Young's schema questionnaire (1990). However, questionnaires should never be used by themselves, as discovery of the underlying structure needs to be a joint endeavor between therapist and patient. Questionnaires are also open to response biases, and, by definition, cannot capture individual meanings and idiosyncratic terminology.

(v) Modifying basic assumptions and core schemata

Methods for modifying core structures are very similar to those used for the evaluation of automatic thoughts, using the same style of socratic questioning and of behavioral tests. They might be classified as cognitive, behavioral, emotional, and inerpersonal methods. A summary is presented below.

(a) *Cognitive methods.* These involve weighing the advantages and disadvantages of thinking in certain ways, for example, "I must do everything perfectly" (see Table 5); examining the evidence for and against core beliefs, such as, "I am worthless"; establishing continua of zero to 100 to rate personal qualities; evaluating the validity of personal rules; contrasting the short- and long-term utility of personal rules; examining the validity of the conclusions drawn at the time when the basic schemata were arrived at in childhood; collecting evidence contrary to the basic schema. Padesky (1990) describes the self-schema as self-prejudice to explain to the patient how the basic schema acts to filter information, so that only negative confirming information

is accepted and processsed, while disconfirming information is either transformed into confirming information or ignored or disqualified. Padesky (1994) describes in detail several cog-

Table 4 Example of "downward arrow" technique to arrive at basic assumptions and core schemata.

Situation: This is Helen's first day at the office	
Emotions: Depressed (60%), anxious (70%)	
Automatic thoughts	
Helen	I'm really dumb. I should have organised myself better.
Therapist ↓	Supposing that were true, what would it mean about you?
Helen	It means that I can never get things right or do things properly.
Therapist ↓	Supposing that were true, what would it mean about you?
Helen	It would mean that people cannot trust me to do things perfectly.
Therapist ↓	Supposing that were true, what would it mean to you?
Helen	It would mean that I am second rate, useless.
Therapist ↓	Supposing that were true, what would it mean?
Helen	It would mean that nobody would respect me.
Therapist ↓	And if nobody respected you, what would it mean?
Helen	It would mean what I've always known—that I am worthless.

nitive change methods and methods for consolidating the new schema (e.g., keeping a positive data log).

(b) *Behavioral methods*. These invlove engaging in activities which disconfirm the basic belief (e.g., do a piece of work in less than the usual time and testing whether not attaining perfection entails social or professional catastrophies); or stopping behaviors which maintain the belief (e.g., stop avoiding meeting people).

(c) *Emotional methods*. These may involve some procedures from Gestalt therapy, for example, role plays of key painful experiences of the past, when the therapist, appropriately briefed by the patient, can play the role of a punishing parent or of an unfair teacher, and the patient plays the role of the child, but with an adult understanding. These role plays are rehearsed in role reversals several times, usually bringing strong emotional responses. Other emotional methods may involve examining key experiences of the past and using reattribution methods to decrease self-blame and guilt which might have been reinforced by critical parents in childhood. Figure 7 below describes the conclusions reached after discussing a patient's sense of responsibility for the unhappiness of her parents.

(d) *Interpersonal methods*. These involve group, marital, or family therapy if indicated; but more usually; the therapist uses the interpersonal relationship in the therapeutic situation to develop ideas about problems in interpersonal style which are then discussed openly, as is usual in cognitive therapy.

6.03.3.3 Developments

The area of cognitive therapy which has developed the most in the 1990s is the methodology for evaluating and modifying schemata. These changes have evolved gradually through theoretical developments (e.g., Teasdale & Barnard, 1993) and through the expansion of cognitive therapy to new areas of psychopathology, in particular to the personality disorders (Beck et al., 1990; Layden et al., 1993; Linehan, 1993; Young, 1990). Similarly, through, the influence of the constructivist approach (Guidano & Liotti, 1983; Mahoney, 1993) and because of the wider application of cognitive therapy, more emphasis is probably put on developmental and interpersonal issues in the formulation of cases. Another area of development is the application of relapse prevention methods at the end of treatment (Wilson, 1992). The importance of this stage of therapy is reflected in the dedication of a whole chapter to this topic in this volume.

Table 5 Weighing the advantages and disadvantages of a dysfunctional basic assumption.

Basic assumptions: I must do everything perfectly, if not, people will not respect me and I am worthless.

Advantages of this belief	*Disadvantages of this belief*
It makes me try hard to do well	It increases my anxiety, so that my performance suffers.
It makes me produce good work and be successful.	It stops me from doing many of the things I would like to do, because I may not succeed.
When something goes well, I feel really good.	It makes me very critical of myself, so that I cannot take pleasure in what I do.
	I cannot afford to let my mistakes be noticed by anyone, and therefore I probably miss out on valuable constructive comments.
	When I get criticized, I become defensive and angry.
	My successes are undermined, because any subsequent failure wipes out their significance.
	I become very intolerant of others. I find so many faults in others, that I cannot be warm and friendly. I will end up without any friends.
	I can never think well of myself because it is impossible to get it right all the time.
	Because I get so upset by failures, I cannot use them as valuable experiences to learn how to do things better next time.

6.03.4 PROCESS OF COGNITIVE THERAPY

A large number of controlled outcome studies, reviewed by Blackburn, Twaddle et al. (1996), attest to the efficacy of cognitive therapy in depression (Blackburn, Bishop, Glen, Whalley, & Christie, 1981; Elkin et al., 1989; Hollon et al., 1992; Murphy, Simons, Wetzel, & Lustman, 1984; Rush, Beck, Kovacs, & Hollon, 1977; Teasdale, Fennell, Hibbert, & Amies, 1984); in general anxiety disorders (Butler, Fennell, Robson, & Gelder, 1991; Durham et al., 1994; Durham & Turvey, 1987; Power et al., 1990); in panic disorder (Barlow, Craske, Cerney, & Klosko, 1989; Beck et al., 1992, 1994; Clark et al., 1994) and to a lesser extent in obsessive-compulsive disorder (Emmelkamp & Beens, 1991; Emmelkamp, Van der Helm, Van Zainten, & Ploghg, 1980; Van Oppen et al., 1995). However, there is little understanding of what are the actual critical components of cognitive therapy in effecting change and most of the work to date is in depression. Relevant studies have been reviewed by Whisman (1993) and by Robins and Hayes (1993). A summary of the main findings is provided here. Research has attempted to differentiate between mediators and moderators of change in cognitive therapy. Mediators are the mechanisms or the patients' characteristics that are changed by treatment and which precede change in the dependent variable of interest (level of depression). In contrast, moderators are the variables that predict treatment outcome, for example therapists' competence level and patients' characteristics (gender, age, diagnosis).

6.03.4.1 Mediators of Change in Cognitive Therapy

Cognitive therapy aims to bring about improvement by changing the hypothesized cognitive components which maintain the disorder. Cognitive changes after treatment have been found to correlate with level of improvement (Blackburn & Bishop, 1983; DeRubeis et al., 1990; Rush, Beck, Kovacs, Weissenburger, & Hollon, 1982; Seligman et al., 1988). Garamoni, Reynolds, Thase, Frank, and Fasiezka (1992) reported that the balance of positive to negative cognitions and related affect changed to an optimal range in responders to cognitive therapy, but not in nonrespondents. Persons and Burns (1985; 1986) also found that changes in negative-automatic thoughts within session were highly correlated with within-session changes in mood. The covariation between change in cognition and change in depression has been found in studies using self-rating measures (Beck, Ward, Mendelson, Mock, & Erbaugh, 1961), as well as observer ratings of depression (Hamilton, 1960).

However, the effect of cognitive therapy on cognitive mediational variables is not unique to cognitive therapy, pharmacotherapy having the same effect (Simons et al., 1984). Blackburn and Bishop (1983) attributed the larger effect of cognitive therapy relative to pharmacotherapy on views of self, the world, and the future to the larger effect on level of depression at the end of treatment in patients treated with cognitive therapy relative to patients treated with pharmacotherapy. Hollon, DeRubeis, and Evans (1987) argued that covariation between change in cognitive variables and change in depression is not sufficient to prove that change in cognitive variables plays a causal mediational role in the recovery process with cognitive therapy. In addition, there must be a primary effect, that is, cognitive change must precede change in depression and experimental manipulation of the degree of change in cognition must correspond to the degree of change in depression. Few studies have succeeded in demonstrating the primary change in cognition. Rush, Kovacs, Beck, Weissenburger, and Hollon (1981), using cross-lagged correlations, found that during the first four of 11 weeks of cognitive therapy, improvement in hopelessness, in view of self, and in mood preceded changes in vegetative and motivational symptoms of depression. No specific pattern of change was found in patients treated with pharmacotherapy. DeRubeis et al. (1990) reported that changes in cognitive variables (attributional style, dysfunctional attitudes, and hopelessness) at midtreatment predicted overall improvement at the end of treatment with cognitive therapy, but not with pharmacotherapy. If this effect is replicated in future studies, these authors' conclusion, that cognitive constructs play a mediational role in cognitive therapy, but that this effect is not sufficient as it was not found in pharmacotherapy which was equally effective, will be an important one in the understanding of the mode of action of cognitive therapy and of medication.

Experimentally, a number of studies have indicated that the manipulation of cognitive content, using the Velten procedure (1968) of reading self-referent sad statements, induces sad mood (Coleman, 1975; Hale & Strickland, 1976; Teasdale & Fogarty, 1979). These studies have been much criticized because of the experimental bias introduced by the inherent demand characteristics of the task. Perhaps more convincingly, Teasdale and Fennell (1982) compared effects on mood produced by 30 minutes of exploration compared with 30 minutes of active modification of depressive thoughts. They found, in a within-subjects design, that active modification led to a greater reduction of self-rated depression.

When cognitive therapy has been broken down into components to analyze the different aspects of cognitive therapy, mixed results have been obtained. McNamara and Horan (1986) found that cognitive procedures reduced depressive cognitions and improved social skills more than behavioral procedures. Jarrett and Nelson (1987) divided the cognitive therapy package into three components: self-monitoring, logical analyses, and hypothesis testing. All subjects received each treatment component in one of two sequences. The results indicated that self-monitoring did not bring about a change in symptoms, but logical analysis and hypothesis testing brought about a decrease in depressive symptoms and in negative automatic thoughts, a better level of interpersonal relationships, and a greater frequency of pleasant activities. The two active components, logical analysis and hypothesis testing, were more effective in combination than singly. Jacobson et al. (1996) randomly allocated 150 outpatients with major depression to partial cognitive therapy (behavioral component and modifying automatic thoughts) or to full cognitive therapy (behavioral component, modifying automatic thoughts, and modifying core schemata). They found partial cognitive therapy as effective as full cognitive therapy at the end of treatment and at six months follow-up. Both the behavioral component and the automatic component were as effective as full cognitive therapy in altering negative thinking and dysfunctional attributional style. These results are in contrast with McNamara and Horan's (1986) and Jarrett and Nelson's (1987) findings, indicating that more work is required in this area.

The debate about what type or level of cognitive change actually is achieved in cognitive therapy is unresolved. Persons (1993), in a theoretical paper, considers whether cognitive therapy changes the basic schemata which are presumed vulnerability factors or only teaches compensatory skills. The two models generate different predictions regarding the timing of change (which would occur earlier in the schema change model) and the generalizability of what is learned in therapy (the compensatory skills model providing more general skills which might provide more protection against future episodes of illness). The two models are empirically testable and answers may be provided in future studies.

6.03.4.2 Moderators of Change in Cognitive Therapy

The Cognitive Therapy Scale (CTS; Young & Beck, 1988) is a 13-item rating scale which evaluates several aspects of cognitive therapy, the therapeutic alliance, adherence to the procedures of cognitive therapy (including the structure and content of therapy), and competence or skill in application of the methods and techniques. The CTS has been found to have adequate psychometric properties (Dobson, Shaw, & Vallis, 1985; Vallis, Shaw, & Dobson, 1986), but the relationship of ratings on the CTS and outcome has not been demonstrated.

The quality of the therapeutic relationship has been found by some researchers to be positively related to outcome (DeRubeis et al., 1990; Persons & Burns, 1985). In contrast, Bercham (1989) found no relationship between therapeutic alliance ratings during early sessions of cognitive therapy and outcome in the treatment of depression. DeRubeis and Feeley (1990) found that the "facilitative" aspects of cognitive therapy (empathy, warmth, and understanding) and a measure of the helping alliance did not predict change in depression level after the sessions in which they were rated. However, ratings of the helping alliance made during later sessions of therapy were related to prior change in depression symptoms.

Several studies have demonstrated that cognitive therapy can be discriminated reliably from other psychotherapies, for example, interpersonal psychotherapy (DeRubeis et al., 1990; DeRubeis, Hollon, Evans, & Bemis, 1982; Hill, O'Grady, & Elkin, 1992), indicating that the procedures of cognitive therapy are specific. Only one study, by DeRubeis and Feeley (1990), has examined the relationship between adherence to different aspects of the treatment protocol and outcome. These authors found that "concrete" and "symptom-focused" methods of cognitive therapy predicted outcome, whereas "abstract" discussions did not.

Level of competence has been reported to be related to outcome (Beckham, 1990; Burns & Nolen-Hoeksema, 1992; Hollon, Shelton, & Davis, 1993), but contrary findings have been reported in psychotherapy (Shapiro et al., 1994). The issue of level of competence of therapists is of evident importance for outcome studies and for training courses.

Since therapy involves a diadic relationship, patient's characteristics may be of equal importance as therapists' characteristics for outcome. Sociodemographic variables have usually been found not to be important in determining response to cognitive therapy, except that married status appears to be a positive predictor (Jarrett, Eaves, Grannemann, & Rush, 1991; Sotsky et al., 1991).

In terms of illness characteristics, several studies have shown that the endogenous subtype of depression responds as well to cognitive therapy as to antidepressant medication (Blackburn et al., 1981; Imber et al., 1990; Kovacs, Rush, Beck, & Hollon, 1981). Severity of depression was found to be a negative predictor of response by Elkin et al. (1989), but other studies have failed to replicate this finding (Hollon et al., 1992; McLean & Taylor, 1992; Thase, Simon, Cahalance, McGreary, & Harden, 1991). Since cognitive therapy targets cognitive dysfunction, it might be hypothesized that cognitive therapy would be relatively more effective than control treatments (e.g., pharmacotherapy) for patients with higher levels of cognitive dysfunction. In a review paper, Rude and Rehm (1991) conclude that research findings do not support this prediction.

In terms of personal characteristics, level of intelligence has not been found to be related to outcome (Haaga et al., 1991) and the presence of a concurrent Axis II disorder (personality disorder) has been found to be related to more residual symptoms of depression at outcome and poorer social functioning (Shea et al., 1990). Simons, Lustman, Wetzel, and Murphy (1985) examined a number of predictor variables in an outcome study of depression and found that a cognitive variable, learned resourcefulness, was the only reliable predictor. High learned resourcefulness (as measured by the Self-Control Schedule; Rosenbaum, 1980) predicted better response to cognitive therapy and low learned resourcefulness predicted better outcome with pharmacotherapy. Learned resourcefulness refers to a set of coping and problem-solving skills that facilitate the monitoring, control, and change of dysfunctional or unpleasant events. However, the finding by Simons et al. (1985) has not been replicated (Beckham, 1989; Jarrett, Giles, Gullion, & Rush, 1991; Kavanagh & Wilson, 1989).

The short preceding review of the process of action of cognitive therapy indicates that findings are limited as they relate primarily to depression. Both mediating and moderating variables remain relatively unclear or unreplicated.

6.03.5 EFFICACY

The efficacy of cognitive therapy relative to other treatment methods has been well demonstrated, as can be seen in the various chapters of this volume relating to specific disorders. Of particular interest is the long-term or prophylactic effect of cognitive therapy. Cognitive therapy aims to decrease psychological vulnerabilities by targeting the underling cognitive structures which are hypothesized to make up these vulnerabilities. Whether it succeeds in doing so by modifying the underlying structures (schemata) or by teaching coping skill (Persons & Miranda, 1992), it would be expected to reduce the likelihood of relapse or recurrence of illness after successful treatment. In general, this expectation has been fulfilled in follow-up studies of depression (Beck et al., 1985; Blackburn et al., 1986; Evans et al., 1991; Kovacs et al., 1981; Shea et al., 1992; Simons et al., 1986). Fewer long-term studies have found the same prophylactic effect in general anxiety (Borkovec & Costello, 1993; Butler et al., 1991; Chambless & Gillis, 1993) and in panic disorder (Clark et al., 1994; Craske, Brown, & Barlow, 1991; Shea, Pilkonis, Cloitre, & Leon, 1994).

Unfortunately, all follow-up studies have been primarily naturalistic, so that no control was exercised on what actually happened to the patients after the end of treatment of the acute episode. However, the data from various studies are sufficiently congruent to indicate that cognitive therapy does have a prophylactic effect. Better controlled studies are awaited.

6.03.6 CONCLUSION

In this chapter, a general overview of the theories and research underlying cognitive therapy has been given. The application of cognitive therapy indicates an on-going cross-fertilization between evolving theories, research, and practice. The fact that cognitive therapy has not remained static since its inception is a healthy sign of a growing and living theory. It is evident that future research is needed in information processing, in the bidirectional interaction between emotion and cognition and in the process of therapy to elucidate many of the issues raised in this chapter which still remain open. Moreover, as the methodology of outcome research improves and assessment measures get more sophisticated, clinicians will be able to make better predictions about which patient responds best to cognitive therapy. The expanding application of cognitive therapy remains to be tested.

6.04.1 INTRODUCTION

Gurman, Kniskern, and Pinsof (1986) defined family therapy as "any psychotherapeutic endeavor that explicitly focuses on altering the interactions between or among family members; and seeks to improve the functioning of the family as a unit, or its subsystems, and/or the functioning of individual members of the family" (p. 565) The term "systemic psychotherapy" is a broader definition that includes, in addition, intervention in other groups and organizations using systems ideas and keeping a relational focus, for example, networking (Dimmock & Dungworth, 1985) and systemic consultation (Boscolo & Bertrando, 1993).

Systemic psychotherapy recognizes the recent important developments in family therapy theory and practice, building on the earlier pioneering work of the family therapists.

6.04.2 FAMILY SYSTEMS THEORY

Family therapy developed during the 1950s and 1960s as practitioners experimented with involving family members in the treatment process. Early observations, such as "see-saw" effects in marriage, where improvements in the psychological well-being of one partner as a result of individual psychotherapy seemed to herald a worsening for the other partner's well-being; or "status quo" effects where improvements in individually treated psychological symptoms were not sustained; or the inability of individual approaches to address relationship difficulties *per se*, led early family therapists to speculate as to the importance of the social and relational context for the genesis and/or maintenance of individual symptomatology. Thus, the family system or kinship network was successfully placed at the center of therapeutic thinking. However, the early practitioners found their practice had developed ahead of their conceptual thinking. They turned to general system theory (von Bertalanffy, 1968) for its potential for application to the study of family process and family therapy.

Systems research is concerned with the concept of self-organized complexity in living systems, a central tenet of which was that a whole functions as a whole through the interdependence of its parts. General system theory attempted to explain how this obtained in the widest variety of systems, spanning the social, physical, and biological world. Thus, the theory attempted to classify systems according to the way the parts were interrelated, and to describe typical patterns of behavior for the different classes of systems as defined.

Within the model of organized complexity, there exists a hierarchy of levels of organization, for example, organelle, cell, tissue, organ, organism, such that each level of organization is more complex than the one below, with each level characterized by emergent properties that do not exist at lower levels and as such are not reducible to previous events. Our example of a biological system is said to have emergent properties, such as reproduction, self-organization, and self-reflective behavior. Systems are described as open if they exchange materials, energies, and information with their environment. Thus, open systems can be considered subsystems of higher order systems, for example, the individual as a member of the family, the family as part of the kinship network, the kinship network as part of a culture, and so on.

In this way, general system theory was adapted to the study of complex organization and interaction in family household groups and kinship networks. A major contribution has been in the study of system adaptability, the balancing of the homeostatic tendency, and the capacity for transformation. The family system is defined in terms of its structure; its structure is defined as the network of relationships amongst its component members; and its relationships are defined in terms of interactions that are mediated by communication, information exchange, and the development and transmission of meaning. Thus, the family system is said to function to develop networks of operations suitable for coping with the varied and changeable environmental inputs and internal stresses to which it is subject.

Family system theorists are concerned with the description of family rules, identifying hierarchies of feedback and control. Feedback or recursive processes are believed to be characteristic of social systems, such as family groups, where family members' output is recognized as input at some later stage. Thus, explanations of behavior embrace circular notions of causality. Boundaries are said to determine system and subsystem membership in family groups, with family rules operating to define who belongs to the subsystem and their roles and tasks within the subsystems. Boundaries are described as more or less open according to the degree of exchange with the system's environment.

General system theory provided a conceptual framework for early attempts to describe complex, time-related interactional behavior amongst family members, for which psychological and sociological theories were not suited. It focused attention on the role of each family member in the maintenance of psychological symptoms and took account of the various social and cultural variables impinging on family groups. The development of individual distress was seen within a contextual, social matrix and the treatment process addressed both individual needs and the needs of other family members. For example, Prince and Jacobson (1995) examined the hypothesis that the treatment for depression in married women needed to address the interpersonal environment. They examined three recent studies which compared behavioral marital therapy for distressed couples with individual cognitive therapy where the women were diagnosed with unipolar depression. They found that both therapeutic approaches were successful in reducing depression at six and twelve month follow-ups, but that the couples therapy was effective in reducing the marital distress.

The application of general system theory to the study of the family has been critiqued extensively (Pam, 1993; Vetere, 1987). Difficulties include a lack of clear conceptual definitions, necessary for operational definitions, and overlap between the *description* and the *explanation* of family system behavior. The conceptual and practical focus on relational processes led to a perceived diminution of the importance of individual emotional experiences and motivations, and the emphasis on circular causality led to a perceived diffusion of responsibility within family groups for unacceptable behaviors, such as violence and abuse. It is debatable to what extent family therapy practitioners took circular causality to mean that victims of violence played a part in the development of violent patterns of behavior for which they were accountable or blamed, or used the concept of circularity to understand how such processes arose. The current position separates the issue of responsibility for violence from the explanation of how violent behaviors occur. A linear moral stance is taken with respect to the responsibility of the perpetrator for the abuse, and then only working therapeutically, using explanations and notions of patterning and circularity, when the perpetrator has admitted responsibility and engaged in a nonviolence contract (Bentovim & Davenport, 1992).

6.04.3 FAMILY LIFE CYCLE THEORY

It has been proposed that family groups pass through phases, whose characteristics are determined by changes within family members, the impact of external events on family members, and the influence of sociocultural norms and requirements (Carter & McGoldrick, 1989). Thus, the family system is seen to move through time, expanding and contracting its membership as individuals join and leave the system. The family is usually a multigenerational system at any time, so that each generation can be influenced by previous and later generations. Special challenges to the family's organization, membership, and belief systems, which may be experienced as stressful, are said to arise at transitional points in family development, such as the birth of children, or young adults establishing their own households, where there is a confluence of external and internal demands for changes, understood and interpreted by family members within the context of transgenerational influences, that is, the handing down of family cultural beliefs, expectations, and practices. So, for example, grandparents might have a similar or different set of expectations to the parents about their involvement in rearing their grandchild, or a young couple might experience some difficulty in establishing what is their province of decision making relative to that of their extended family.

Carter and McGoldrick (1989) delineate a typical set of stages in development as follows: courting couples, couples without children, childbearing families with children in the preschool years, families with school-age children, families with adolescents at home, families with adolescents beginning to evolve separate lives, families with adult children, and families in retirement. Family members are said to face different challenges at different phases of the life cycle, with different expectations of self and others according to external demands and maturational and social demands for change and adaptation.

The life cycle stage model has been critiqued as applying to Western, middle-class, nuclear families with less relevance for different family forms, some ethnic groupings, poor families, and so on (Vetere & Gale, 1987). Certainly, if we accept the concept that a family is made up of different individuals at different stages of growth, the concept of family is difficult to grasp within this model. However, as a model it should purport to show how transitions affect adaptation, which demands a longitudinal perspective within research. The model, while not easy to put to the test, has construct validity and its implications for other theories of family functioning is considerable.

Definition of the family presents considerable difficulties for family researchers and therapists (Trost, 1990). Trost's survey of general public definitions of the family revealed little agreement, for example, with opinion literally divided over whether a heterosexual marital couple without children constituted a family or whether a lone parent and child constituted a family. The criteria for definition of the family used by respondents to the survey were legal ties, biological relatedness, common residence, and psychological significance, another concept which is difficult to define. In addition these criteria were weighted differently by the respondents. Thus, family researchers and therapists differentiate between definition of an individual's family, where an individual's perceptions of family life are accorded prominence, and definition of the family unit, which is believed necessary for the understanding of the development of family groups over time, family-wide difficulties, impact of traumatic effects on family processes, and so on. For many purposes therapists and researchers use the family household as the defining criterion.

A fully comprehensive theory of family functioning is not available (Burr, Hill, Nye, & Reiss, 1979a, 1979b). Family therapy approaches involve a range of schools and theories. The rationale for family therapy assumes that most individuals are born into and develop in the context of family groups. The family is seen as the cradle and web of emotional development and the early source of our attitudes and beliefs about ourselves, our relationships, our past, present, and future circumstances. The family is the origin of our basic patterns of social interaction and interpersonal adjustment. Thus, the system that is seen to create and support patterns of behavior may be the means of describing, assessing, and changing interpersonal behavior.

Family therapy is said to be indicated:

(i) when a child or adolescent is the referred person;

(ii) when family members define the problem as a family issue, such as relationship and communication difficulties;

(iii) when relationship difficulties threaten the future of the couple relationship or the adequate care of the children;

(iv) when the family has experienced recent stress, such as death, serious illness or injury, loss of employment, "leaving home" issues;

(v) when psychological symptoms have secondary gain effects; and

(vi) when family members become organized into "helping" with the problem in such a way that the attempted solutions become problematic themselves.

Family therapy is contra-indicated:

(i) by practical limitations, such as the unavailability of key members or the unavailability of an experienced therapist;

(ii) when family members are "sentenced" to therapy by the courts as an alternative to legal proceedings and motivation to participate in therapy is highly ambivalent;

(iii) when a family presents "too late";

(iv) when mediation might be more appropriate;

(v) in circumstances of precarious emotional equilibrium or emotional deprivation, when family therapy is more appropriately considered part of a larger intervention programme, that might include individual therapy, social supports, and practical aid.

6.04.4 SOME MAJOR SCHOOLS OF FAMILY THERAPY AND SYSTEMIC PRACTICE

The family systems tradition and the associated discipline of family psychology have given rise to a number of different schools of family therapy, such as structural (Minuchin & Fishman, 1981), strategic/problem solving (Haley, 1976; de Shazer et al., 1986; Weakland, Fisch, Watzlawick, & Bodin, 1974), Milan (Selvini-Palazolli, Boscolo, Cecchin, & Prata, 1980a), transgenerational (Lieberman, 1979), constructivist and social constructionist (Andersen, 1987; Hoffman, 1993), and narrative (Freedman & Combs, 1996).

6.04.4.1 Structural Family Therapy

Structural family therapy (Minuchin, 1974; Minuchin & Fishman, 1981) is a body of theory and techniques that approaches individuals in their social contexts and conceptualizes family interactions as habitual and sequential. Structure refers to the family's organizational characteristics, the subsystems it contains, and the rules which govern interactional patterns among family members. An aim of therapy is to alter organizational patterns, particularly where modes of communication among family members are seen to be dysfunctional. When the structure of the family group is transformed, the positions of members in that group are altered accordingly. As a result, each individual's experiences change. Thus, individual change is predicated upon system change.

Structural theory has five principal features:

(i) The family is a system which operates through transactional patterns, that is, repeated transactions establish patterns of how, when, and to whom to relate, and these patterns underpin the system.

(ii) The functions of the family system are carried out by bounded subsystems.

(iii) Such subsystems are made up of individuals on a temporary or permanent basis, and members can be part of one or more subsystems, within which their roles will differ.

(iv) Subsystems are hierarchically organized in a way which regulates power structure within and between subsystems.

(v) Cohesiveness and adaptability are key characteristics of the family.

Structural family therapy is described in three stages: joining, middle therapy, and termination. Therapy is believed to be effective when the therapist forms a new system with the family. The therapist relies heavily on techniques of joining and accommodation, such as planned support for the existing family structure, tracking the process and content of family members' communication, and accommodating to the range and style of family affect. Middle therapy interventions confront and challenge family members at the three levels of symptomatic behavior, family structure, and family members' beliefs, in the attempt to create therapeutic change. Interventions can include the enactment and re-enactment of interactional patterns, the development of negotiation and problem-solving skills, reinforcing parental authority, reframing interpersonal dilemmas, creating opportunities for empathic appreciation of others' perspectives and needs, providing support for change, and negotiating tasks within and between sessions. The therapy contract is terminated when the family members have rehearsed their ability to solve new problems and have had the opportunity to solve earlier ones.

6.04.4.2 Milan Family Therapy

Milan family therapy approaches the family as a history-containing system with entrenched meanings (Selvini-Palazolli et al., 1980a). It is based on Bateson's (1972) circular epistemology and focuses on information and difference. The Milan family therapist searches for differences—in behavior, in relationships and in the way family members perceive and construe events—and connections and links between ideas, behaviors, relationships and events. The approach assumes that these connections hold the system in balance.

Milan family therapy has been described as "long brief therapy" (Tomm, 1984) with sessions usually held monthly over a one-year period. The therapists work as a team, with two therapists usually interviewing the family and observed by two colleagues from behind the one-way screen. The session format often consists of an interview, followed by a break when the two interviewing therapists retire behind the one-way screen to consult with their colleagues, and finishing with the delivery of a message to the family. The Milan interviewing techniques consist of hypothesizing, circular questioning, neutrality, positive connotation, and the use of rituals. Hypothesizing refers to the presession formulation when the team hypothesizes about what might be maintaining the family problems. Hypothesizing helps organize incoming information during the family session, and is constructed continuously as a result of feedback received from the family to the questioning developed from the original hypotheses. Circularity throughout the system is stressed; problems and events are depicted as interpersonal, such that a problem can be seen as an event between two people.

The use of circular questioning in the family session reflects and is guided by systemic hypothesizing. Every question explores differences in family members' perceptions about events, relationships, beliefs, and the connections between them, illustrating Bateson's ideas about difference, information, and circularity. For example, different family members might be asked about their attitudes to a particular event, allowing the therapist to focus on difference without being too confrontational, exploring differences in meaning afforded to the same event. Triadic questioning, asking one person for their view of the relationship between two other family members, often produces changes in relationships as well as providing information for the therapists. Family members learn to think in circular fashion and to become observers of family process in a way that allows different views to be enlightening and helpful. Neutrality refers to the therapist's attempts to be even-handed in the session, allied to all without getting involved in family coalitions or alliances. It does not mean that the therapist is indifferent or ethically neutral, especially when working with abuse and violence in families. The therapist is more concerned with understanding the meanings in the system than with attempts to change the system. This is believed to be the process through which change occurs, that is, by not intervening to direct family members, the therapist encourages the family members' ability to generate their own solutions.

Positive connotation is a form of reframing, whereby symptomatic behavior is seen as positive or helpful because it keeps the system in balance and furthers family cohesiveness. Thus, the intention behind symptomatic behavior is seen in a good light, preparing the family for a paradoxical injunction around the need for family cohesion apparently to require the presence of symptomatic behavior. Family rituals often mark and facilitate developmental transitions in family life. They may be developed as part of therapy to help clarify family dilemmas and promote new ways of doing things which may help family members change their views and attitudes and see different options for behavior.

6.04.4.3 Range of Therapeutic Techniques

All family therapists use a range of therapeutic techniques, which vary somewhat according to school, such as problem-solving techniques, solution-focused techniques, directive techniques (e.g., enactment, restructuring boundaries), neutral techniques (e.g., emphasizing patterns in relationships), cognitive intervention (e.g., reframing of relationships), between-session activity (e.g., tasks, rituals), narrative and restorying techniques.

The hallmark of the family systems approaches has been the development of methods of live supervision and consultation (Campbell, Draper, & Huffington, 1989), such as the use of video and live observation teams located behind one-way screens (Madanes, 1984; Whiffen & Byng-Hall, 1982), in-room supervision (Kingston & Smith, 1983), reflecting teams and reflective practice (Andersen, 1987), and so on.

6.04.5 DEVELOPMENTS IN FAMILY THERAPY THEORY AND PRACTICE

Contemporary systemic thinking and practice represents a knitting together of different theoretical positions and concepts, such as: positive and negative feedback processes (recursiveness); hierarchy of system levels; boundaries (open and closed); pattern in relationships and meaning; family life cycle; communication theory; stability and change processes; symptomatic and system change; the position of the observer in the system; feminist critiques of gender, power, and inequality; narrative approaches; and solution focused approaches. Increased emphasis on the conceptual integration of different family therapy approaches (Burnham, 1992; Liddle, 1991a), the fit between therapist style and preferred models, and the needs of the family members and collaboration in the therapy endeavor (Hoffman, 1993) can be traced to recent theoretical developments in the field. For example, Goldner, Penn, Sheinberg, and Walker (1990) describe the integration of social learning, psychodynamic, sociopolitical, and systemic ideas in their therapeutic work with male violence in couple relationships.

Current systemic thinking and practices have been strongly influenced by the feminist-led critiques of power and inequality in family life (Perelberg & Miller, 1990), the postmodern developments of constructivism and social constructionism, and the emergence of user-friendly approaches to family therapy (Reimers & Treacher, 1995).

6.04.5.1 Feminist-led Critiques

The feminist-led critiques of family systems theory and practice heralded extensive rethinking and revision of the assumptions and models of working with families. Generation had long been recognized in the field as an important organizing feature of family life. Feminist family therapists pointed out the dimension of gender as another organizing feature of family life and proceeded to analyze and deconstruct the concept of power and gender-based access to sources of power (Hare-Mustin, 1986; Goldner, 1985, 1988). The sociological structural-functional theories of Parsons, which posited that men held instrumental roles in family life and women held expressive roles, no longer went unchallenged. Thus, family therapy was seen as a political process, in that it dealt with the allocation and distribution of power among family members, the therapist and family members, and so on.

Some significant contributions from feminist theorizing which influenced the development of family therapy thinking and practice included:

(i) recognition that men and women have different experiences of self, of others, and of life;

(ii) recognition that men's experiences had been more widely articulated than women's, which was underrepresented;

(iii) recognition that women do not have equality of opportunity, despite recent legislation in both the UK and USA (Central Statistical Office, 1990);

(iv) placing the family in a historical context and challenging accepted views of the family; and

(v) calling for a re-examination of family life, such as redistributing household and "mothering" responsibilities, validating nontraditional sexual and living arrangements, campaigning for reproductive rights, and calling for an end to women's economic dependence on men.

Such theorizing highlighted how slow family therapists had been to identify the links between social inequalities and psychological distress.

Williams and Watson (1987) have argued that the issue of asserting authority and power and having it acknowledged and respected is particularly problematic for women in a variety of situations. In addition to the relative lack of experience with leadership roles and the overt use of power in public life and social institutions, most women are reared in a multitude of nonverbal behaviors that communicate submission and indecision. They suggest that men and women traditionally have had differential access to types of interpersonal power, and these means of access are determined largely by sex-role stereotypes and expectations. Women are said to influence others more indirectly and to rely on their own personal resources including attractiveness, kindness, empathy, warmth, and close interpersonal relationships for the exercise of referent power. Men are said to utilize more direct means of influence, relying on a different set of resources, such as strength, skill, and competence and tend to be more indifferent to the interpersonal/intimate dimension for the exercise of instrumental/expert power.

The feminist critiques of differential gender-based access to power, and the new focus on gender as a once hidden dimension of family life, had enormous implications for the practice of family therapy. A gender-sensitive approach to family therapy developed, not as a set of specific skills or techniques, but as a process between therapist and family members which provided an opportunity for all family members to negotiate both their individual and system needs. Thus family therapists strived to be more aware of their own values regarding gender, as they are expressed in training, therapy and supervision; and began looking at the extent to which our ideas about differences between men and women are based on sexist stereotypes (Wheeler, Avis, Miller, & Chaney, 1989).

Family therapists are curious about the ways in which gender roles and stereotyping affect each individual in the family, the relationships between family members, the relationships between family members and other social institutions, and relationships between family members and the therapist (Gregory & Leslie, 1996). They ask questions that make explicit the issues, expectations, decisions, and behaviors that demonstrate the degree to which equality of opportunity and reciprocity exist between men and women in the family. Using analyses of interpersonal power, family therapists formulate questions about how the presence or withdrawal of different sources of power affect everyday processes, such as decision making, negotiation, and conflict resolution. Family therapists can use positive reframing and relabeling to shift the conceptual and emotional perspective on an individual or a relationship. For example, what may have been seen as personal inadequacy may be reinterpreted as socially prescribed, by exploring with men and women what they have been taught about their own gender roles and each other's, such as passivity as a model for female behavior or emotional impassivity as a model for male behavior. Gender-sensitive family therapists can facilitate consideration of a wider range of perspectives, behavior, and solutions that are less constrained by more traditional definitions of roles and personal identity. For example, when discussing parental teamwork and shared responsibilities, attention can be paid to the implications for both partners by checking that the woman is willing to share parental responsibility and has other ways of expressing her competence, and that the man is willing to bear the cost in the workplace of being more involved in the family. Family therapists can use their "gendered selves" in therapy in a therapeutic manner, for example, by modeling alternatives to traditional roles.

Recently, there has been a shift from a woman-centred focus to gender-sensitive family therapy to an incorporation of analyses of male psychological experience (Frosch, 1992; Mason & Mason, 1990). The debate on how to engage men/fathers in the therapy process has been informed by research which seems to indicate that men are less likely to seek help with emotional concerns than women (Verbrugge, 1985) and that when they do seek help, their problems are at a more serious stage of development (O'Brien, 1990). The risk of men not being engaged is heightened: (i) if family therapy is seen to take place in "women's time" and in a "woman's world," so to speak; (ii) if men are slower on the whole than women to perceive indicators of relationship difficulties, and (iii) if expressive differences between men and women leave them believing that fathers get involved in therapy only when family distress is very high. The greater difficulty in engaging men in the therapy process leaves women shouldering the burden of the responsibility for change, with fathers, albeit inadvertently, made peripheral.

Issues of culture and race have also been critically examined in the practice of systemic family therapists (Lau, 1987). Similar distinctions have been drawn between cultural awareness and culturally sensitive practices and the role of training in promoting sensitive practice (Hardy & Laszloffy, 1995). Reflexivity in the training process has led to examination of how therapists' cultural identities (which includes consideration of ethnicity, gender, social class, age, and so on) influence their understanding and acceptance of those who are both culturally similar and dissimilar. Falicov (1988) suggests that one way to help family therapists in training to think culturally is for them to interview a nonclinic family of a distinct ethnic or socioeconomic group. To date, the literature consists of theoretical critiques with clinical case descriptions of culturally sensitive practice.

6.04.5.2 Constructivism and Social Constructionism

Constructivism and social constructionism have had a significant impact on contemporary systemic thinking and practice (Hayward, 1996). A postmodern perspective embraces issues of meaning and language, narrative, politics, and practices of power. Family therapy theory increasingly attends to the interpretive meaning-making dimension of experience and the multiple contexts in which it occurs and evolves (Cronen & Pearce, 1985). The usefulness of systemic metaphors of family life has been well-documented; their further development has been prompted by the interest in family members' beliefs and stories embedded in language, with family members' ability to reconstrue their worlds in accordance with values and aspirations seen as the central impetus to change (White & Epston, 1990). This contrasts with earlier notions of change in the field, where change at the level of a relationship was seen to lead to change in an individual's felt experience. Anderson and Goolishian (1988) argue that we are dialogical beings who evolve knowledge and meaning and attribute meaning to action through conversation and other forms of social interaction. These ideas suggest that we construct stories or accounts about ourselves, others, and our relationships through social interaction. The major implication of these ideas is to suggest that the therapist's task is to help family members construct more useful stories about themselves and their relationships, for example, by restorying the past and altering the definition of the problem to change its meaning and change its perceived effect on the present.

The critical evaluation of systemic ideas and practice, alongside the recognition of "observer-created reality" has led to the development of reflective practice and reflecting teams (Friedman, 1995). Deriving from the work of Andersen (1987) and colleagues, reflecting team practices illustrate the notion of observing systems and the position of the observer in the system. Reflecting team practice assumes that the therapist and family form a new system during the process of therapy and that the supervising reflecting team can observe and reflect on the therapist/family system, family dilemmas and problems, creating an enriched image of the family and fresh perspectives on their problems and potential solutions. Since family members are invited to listen to the conversation of the reflecting team one or two times during each therapy session, family members themselves assume the position of the observer whilst listening, and when subsequently invited to comment on the reflecting team's conversation, we see an iterative process of both therapist's and family members' views and perspectives folding back on each other, much as in the way one might knead bread dough, as pointed out by Lax (1989).

Andersen first outlined the reflecting team in his 1987 article. He suggested that the working assumptions of the reflecting team included the following:

(i) The observer generates many of the views and distinctions we call "reality," with many possible interpretations present in those distinctions.

(ii) When people share their views, each person hears many different versions of this "reality," and these shared views constitute an "ecology of ideas."

(iii) At any point in time, people can only respond or take part in interactions that are within or partially within their known repertory and experience.

(iv) Sharing different versions of the same world or reality creates the conditions for "stuck" family systems to change, as family members realize that they have more than one perspective, option, or solution available to them.

A fundamental tenet of this approach is that information needs to be shared rather than withheld. This view is held in common with "user-friendly" approaches to family therapy, discussed below.

There are several different guidelines available to the practicalities of reflecting team practice, although they all agree that discussion should positively connote family members' motivations where ethically feasible, and contributors to the reflecting team discussion should build their comments on previous comments so a coherent account emerges during the reflection. The theory and research underpinning this approach is still in the early stages of development. Jenkins (1996) has both critiqued the approach and begun research into the theoretical assumptions, techniques, model of change, indications and contra-indications, using the Delphi technique.

6.04.5.3 User-friendly Approaches

User-friendly approaches to family therapy (Reimers & Treacher, 1995) developed in the UK in direct response to both a perceived diminution in significance of individual subjectivity within some areas of family systems theorizing and a lack of research attention to the experiences of family members in therapy. A recent book by Howe (1989) put forward some devastating criticisms of family therapy. Howe interviewed a small sample of families offered therapy by a team of social workers in social services in the UK. The therapy was a mix of brief strategic and Milan approaches undertaken by a single therapist, connected to a supervising team by closed circuit television and an ear bug. The majority of family members interviewed found the hi-tech approach very alienating and objected to "their" therapist apparently being controlled by some all-seeing yet unknown team.

Howe's book was helpful in that it mobilized a response to alienating practices, yet was flawed in that he failed to acknowledge the many developments in family systems theory and practice, not least of which is a longstanding debate on the ethics of family therapy thinking (Walrond-Skinner & Watson, 1987) and the necessity for therapy to be both ethically and politically defensible (Waldegrave, 1990).

User-friendly approaches recognize that many family members find it very distressing and problematic to come to therapy. Thus, it places a premium on providing adequate information about therapy and pays attention to convening and engaging family members (Treacher & Carpenter, 1983). The relationship of the therapeutic alliance to treatment effectiveness has not been researched in the field of family systems therapy anywhere near as extensively as in the individual psychotherapies, where the therapeutic alliance is held to be a common factor underlying much of effective helping. Research conducted by Bennun (1989) found that fathers were more likely to engage in therapy if they perceived the therapist to be competent, to show a positive liking for the family and to have a problem-solving orientation, whereas mothers preferred therapists to provide an opportunity for the airing of common concerns amongst the family members. Interestingly there seems to be a crossover effect in middle therapy, where mothers preferred a problem-solving approach and fathers had come to appreciate "just talking."

The effect of the therapist's race and gender on the engagement process has received little empirical attention in the family therapy literature, despite its prominence in family therapy discourse over the 1990s. Preliminary research by Gregory and Leslie (1996) with 63 adult heterosexual couples suggests that black females rate their initial sessions more negatively than white females when seeing a white therapist, and that black men had a more positive response than white men to the initial sessions, regardless of the race of the therapist. These differences decreased over time. They found no significant effects for gender of the therapist, which is consistent with the very limited research to date. Gregory and Leslie speculate as to the role of perceived racial difference in engaging family members in therapy and call for the identification of procedures which enhance the probability of family members staying in therapy.

6.04.6 RAPPROCHEMENT WITH OTHER THEORETICAL APPROACHES

Family systems models and practice differ from individual psychotherapeutic approaches because they focus primarily on relationships. They emphasize relationships between people, events, beliefs, behaviors, and so on, as opposed to emphasizing the internal world of individuals, as in individual psychotherapeutic models. Thus, the emphasis in family systems models of the creation of meaning through interaction is different from a primary focus on the cognition of the individual. The understanding of psychological symptoms is rooted in explanations of interactional process. For example, individual development is conceptualized as a complex series of relationships which extend beyond the individual, so a child's development is influenced by the child's relationship with the mother, the mother's relationship with her partner, extended family relationships, prevailing economic and political conditions, and so on, in a rich contextual interplay of different system levels. It is assumed that individual development and maturation are important and the systemic approach focuses on how development is understood and how these meanings affect relationships. For example, a family systems approach recognizes the importance of the different meanings attached to a child's genetic condition and how those meanings might influence relationships.

6.04.6.1 Psychodynamic Influences

Psychodynamic ideas have long informed family systems theory and practice as exemplified in the work of Ackerman (1958), Framo (1982), and Skynner (1976). The psychodynamic view of personal motivation and sources of anxiety and psychological discomfort has been generalized to the level of family group functioning. The psychodynamic systems approach seeks to understand how intrapersonal conflicts and motivations interlock and are expressed at the interpersonal level, with a specific focus on how such interlocking affects the development and expression of psychological symptoms in family members. Proponents of this approach would be interested in how couples bring to their relationship separate psychological heritages rooted in their past parent–child relationships and the extent to which past patterns of relating and introjection influence the current relationship. Applications in practice would seek to understand the extent to which such past attachments are problematic for family members in their current relationships and, by using processes of insight, attempt to bring about change in family members' relationships. Goldenberg and Goldenberg (1991) summarize the main differences between psychodynamic approaches to family therapy and systemic approaches in the differing emphasis on the role of past experiences and unconscious processes; the emphasis on insight- vs. action-oriented techniques; the role of the therapist in making interpretations of individual and family behavior patterns; and the major focus on the individual, in which the way family members feel about each other is emphasized.

Wachtel and Wachtel (1986), writing from the perspective of individual psychodynamic psychotherapists, suggest a number of ways in which systemic ideas can inform the thinking and practice of individual psychotherapists. They recommend that individual therapists explore the systemic meaning of psychological symptoms by asking such questions as:

(i) What is the functional significance of the individual's symptom(s) for the family as a whole?

(ii) How would the family be stressed if the individual were to change?

(iii) Does the symptom serve to restabilize a family whose stability has been threatened?

(iv) Is the symptom a result of an attempted solution to the problem that has in some sense "backfired" and itself become the problem?

(v) Is the symptomatic individual acting out someone else's distress?

Such questions serve to contextualize our understanding of the meaning of symptoms within the individual's significant emotional relationships and puts the individual's problems in a larger framework.

Wachtel and Wachtel also recommend the use of genograms (see Section 6.04.7) in individual psychotherapy. Genograms are useful tools for exploring the transmission of multigenerational patterns and influences, and provide a way of gathering information about an individual's implicit and explicit assumptions, wishes, fears, and values. Wachtel and Wachtel use the genogram like a projective test, a map of the unconscious. In addition they advocate the use of active interventions in individual therapy as developed in family therapy, for example, setting tasks (both individual and systems-oriented); devising rituals of celebration, mourning, and healing; using role play and role reversal interventions systemically; using systemic reframing and paradoxical tasks that embody collaboration; and predicting relapses. Finally, they recommend meeting "the cast of characters," such as adult siblings and partners, rather than engaging them in the therapeutic process itself, with the following possible benefits: correcting the tendency to blame, sampling the individual's interactional style, helping the system become more receptive to individual change, and helping to reconstruct the past.

6.04.6.2 Cognitive Behavior Therapy Influences

Behavior therapists and cognitive behavior therapists are interested increasingly in the utility of family systems ideas and practices. Emmelkamp and Foa (1983) have written about three sources of treatment failure, one of which is the neglect of, and/or the incomplete assessment of, the social contingencies and factors affecting clients' problems, in particular the extent to which a client's behavior is entrenched in habitual and longstanding patterns of family interactions and expectations. The recognition that some treatment failures might be the result of incomplete assessment of powerful social contingencies has led some cognitive therapists to address the question of what additional help clients might need in order to benefit from their therapies. Bandura and Goldman (1995) describe how they developed a family systems and cognitive behavioral analysis for use during assessment to address the above question. They recognize that family systems models and cognitive behavioral models have different theoretical underpinnings and do not attempt any theoretical integration. Instead they point to the areas of overlap and how the overlap can be useful in aspects such as the joint emphasis on beliefs and rule systems governing behavior, the importance of attributions and expectations in perceptions of self and others and the recognition of options for change, and the emphasis on problem-solving patterns and the significance of interpersonal contingencies to the understanding of symptomatic behavior. Thus in therapy, the focus on training in cognitive and behavioral skills to improve and enhance adaptive coping can involve the modification of environmental contingencies that influence clients' problems. This is an interesting and useful area of overlap, they would argue, because the family systems approaches also focus on interrupting interactional sequences that are thought to influence symptomatic behavior. Some of these interactional sequences are thought not to be reducible to the level of individual behavior as they are unique to systems functioning, examples are communication processes, power and hierarchy, patterns of disengagement and overinvolvement. Family systems ideas can thus help cognitive behavior therapists expand their functional analyses to include extended interactional analyses underpinned by models of circular causality rather than the linear models of reinforcement contingencies. Systemic analyses and practices can be used to help understand and overcome difficulties experienced by clients during the therapeutic change process, such as the broader costs associated with change, the client's involvement in familywide dilemmas, and the influence of family process on the content and function of schemata.

6.04.7 ASSESSMENT IN FAMILY THERAPY AND SYSTEMIC PRACTICE

The current and most widely used diagnostic system, the *Diagnostic and statistical manual of mental disorders* (4th ed., *DSM-IV*) (American Psychiatric Association, 1994), assesses and diagnoses individual psychopathology, and largely ignores the significance of interpersonal context to the development and maintenance of psychological problems. The marital and family therapies are not covered by third party insurance payments in the UK and the USA, despite the overwhelming evidence of their efficacy. Assessing systems of individuals demands more complex methodology than individual assessment and differs in the following ways. Assessment in family therapy is an ongoing process, occurring simultaneously with treatment. It is based on an understanding of multiple levels of systems hierarchy and feedback processes within and between levels. Assessment guides intervention. It can be conducted either as a clinical process through interviewing and observation or as formal psychometric procedure using both "insider" and "outsider" reports.

Minuchin (1984) writes that for therapy to be effective and for assessment to take place, the therapist needs to form a new system with the family: the therapist plus family system. In this, the therapist relies on techniques of accommodation and joining. Accommodation is the adjustment of the therapist to the family system. Aspects of accommodation are: *maintenance*, or planned support of the existing family structure; *tracking*, following the content and process of the family communication; and *accommodating* to the family's style and range of affect. Joining is the therapist's own method and style of helping to form the new therapist plus family system, so that the therapist does not lose the position of facilitator.

The areas for assessment in systemic work with families cover the following:

(i) the family's structure of subsystems, roles and boundaries, preferred transactional patterns, and available alternatives;

(ii) family members' strengths, flexibility, and capacity for change as revealed by responses to changing circumstances, past and present;

(iii) family members' perceptions of and sensitivity to each other's needs, behaviors, attitudes, and so on;

(iv) the context of family life, with specific reference to sources of support and sources of stress;

(v) both family and family members' life cycle stages and perceived expectations and tasks; and

(vi) the meaning and significance of symptomatic behavior for family members.

The emphasis on areas of assessment will vary according to the school of therapy. Common pitfalls of assessment include ignoring the developmental process, ignoring some family subsystem, and joining and supporting some family members at the expense of others. Gurman and Kniskern (1981) suggest that all family assessments should make clear at what organizational and psychological level the assessment is conducted, how soon therapy will follow assessment, and the relationship between the different methods for collecting data and the means by which the data should be collated.

Selvini-Palazolli, Boscolo, Cecchin, and Prata (1980b) paved the way for including the referrer in the assessment process, partly to prevent the waste of family and staff time with inappropriate or ill-prepared referrals. Referrers are often invited to preliminary consultation meetings with family members and the therapy team or wider network meetings to establish who in the system wants the referral and any differing views and expectations of the referral. The importance of thinking of referrers systemically as part of the process of convening, engaging, and assessing families has tended to lead to a decline in nonattendance rates (Reimers & Treacher, 1995).

Lieberman (1995) and his colleagues at the Prudence Skynner Family Therapy Clinic have developed an assessment and observation form that is used by both observing team members and the therapist to collate their views after the first family interview. They adapted the Current State Family Assessment (Loader, Burck, Kinston, & Bentovim, 1980) into five separate areas of observation:

(i) process:

(a) communication patterns, such as interruptions, listening, speaking for self and others, contradictory verbal and nonverbal messages;

(b) family atmosphere, such as the predominant mood, whether it is shared by all, what makes it change;

(c) family alliances, such as rigid vs. flexible alliances, presence of conflict and problem solving, scapegoating;

(d) feelings, such as the range, intensity and expression of feelings, presence of empathy;

(e) family boundaries, such as rigid or diffuse generational boundaries, cross-generational alliances, parental role responsibilities, differentiation, and connectedness;

(ii) family seating arrangements;
(iii) content of the interview;
(iv) formulation and themes; and
(v) feedback and tasks given to the family.

A popular atheoretical assessment tool used by family therapists is the genogram, derived from the work of the transgenerational family therapists (McGoldrick & Gerson, 1985). As many families are made up of many people experiencing a multitude of events across many generations, recording this information in a concise and coherent way can be difficult. The genogram provides a vehicle for recording social, emotional, and demographic data across the generations, such as births, deaths, marriages, divorces, life events, emotional connectedness, and so on. It provides a means of exploring the meaning and impact of events across the generations, engaging all family members in the telling. Thus, the process of constructing a genogram allows the therapist and team to contextualize such assessment questions as "what is the current family problem?," "what factors maintain the problem?," "why do family members come for therapy now?," "what are their expectations of therapy and the therapist?," "how have they tried to solve the problem previously?" within an understanding of background data on the characteristics of both the household family group and extended family network.

It has been noted by many beginning family therapists that constructing a genogram is a way of putting family members at their ease in the early stages of therapy, not to mention helping to reduce the anxiety of the therapist. It is a visual and active method that concentrates the attention of all participants, and provides a rationale for negotiating change. The construction of a genogram also has strong therapeutic influence as it can be used to reframe behaviors, events, relationships, and time connections; to make links across the generations and across emotional cut-offs; and to normalize some perceptions. It may facilitate alternate interpretations of a family's experience and point the way to new possibilities in the future.

Other more formal, psychometric assessment methods are available, such as the Beavers Systems Model scales (Beavers & Hampson, 1990). These include the Beavers Interactional Competence and Style scales and the Self-Report Family Inventory. The Competence and Style scales are completed by observers, using videotaped family behavior as the basis of their ratings and the Self-Report Inventory is completed by all family members above the age of 12. The Competence scale is a 13-item structured observational rating scale, with ratings derived from trained observers' evaluations of family interaction over a 10 minute period. The scale evolved from general system theory and studies of well-functioning vs. dysfunctional families. Competence is defined broadly as how well the family performs its necessary tasks, such as providing support and nurturance, establishing effective generational boundaries and leadership, promoting developmental separation and autonomy of offspring, negotiating conflict, and communicating effectively.

The Style scale is a nine-item observational rating scale. The Style dimension represents elements of enmeshment and disengagement at its extreme points, such as extremes in binding and expelling patterns; and affective patterns, such as subdued conflict where anger is threatening vs. open conflicts and hostility. Families at similar "competence" levels may show different functional "styles" of relating. The model assumes that competence in small tasks is related to competence in larger domains of living. The Self-Report Family Inventory is a 36-item self-report scale and measures the major elements of family competence and style, the cornerstones of the Beavers Model. The scales have been developed during 30 years of research into normal family functioning. The internal consistency of the scales, their construct validity and inter-rater reliability have been extensively researched and demonstrate acceptable levels of reliability. Such rigorous attention to issues of reliability and validity requires considerable investment in the training of raters. Most family therapists and supervising teams are unable to invest such resources in training, so the more formal psychometric scales are rarely used in day-to-day practice, mainly being used in research trials. Family therapists rely on clinical interviewing and observation, teamwork, knowledge and experience of family patterns for the assessment and formulation of family difficulties, sometimes supplementing their assessment with more formal procedures.

Termination of therapy will be discussed here as an assessment issue because the iterative and interactive nature of assessment and formulation in part determines the decision to end therapy. Theorizing and empirical research on ending therapy is under-represented in the family therapy field compared to the other psychotherapies (Treacher, 1989). Since family therapy was developed by and is often practiced by clinicians trained in other modes of therapy, notably individual therapies, there is a tendency in the family therapy literature to assume knowledge of both convening and engaging issues and termination issues in family therapy. Readiness for termination is assessed when family members resolve or learn to cope with the presenting difficulties, when they demonstrate increased independence and/or cooperation, when they display more "open" styles of communication, when they report an increased sense of security and show greater flexibility in performing family roles. According to the orientation of the family therapist and team, they will typically review whether family members' expectations of the therapy process have been met, summarize the treatment process and enquire about helpful and unhelpful aspects of the therapy, predict and rehearse future coping in similar situations, and offer a follow-up meeting far enough ahead for the family members to have tested out their newfound confidence.

6.04.8 THE PROCESS OF CHANGE IN FAMILY THERAPY

The main change mechanisms in family therapy are considered to be at the symptomatic level, the level of family structure, and the level of beliefs held individually and collectively. The different schools vary in their emphases. Structural therapy posits change in individual experience as a result of change at the level of the family's organizational structure. For example, a child's experience of parenting is said to change if the two parents learn how to work as a team rather than undermining each other's decisions. Strategic and brief therapies focus on symptomatic change, and use an understanding of interpersonal dilemmas and difficulties as ineffective solutions to problems that are maintained because people are unable to generate alternative solutions. Milan therapy uses intervention questioning to identify and highlight connections between beliefs, behaviors, and relationships, with change occurring as a result of the development of new perspectives within relationships. These changes are achieved using a range of techniques, described earlier in the chapter. The following discussion will consider how the family therapy process studies have investigated the processes hypothesized to bring about change and actual change.

Family therapy process studies investigate change mechanisms common to the various types of family therapy. To date, most research has focused on family therapy outcomes, demonstrating the efficacy of family therapy for many different psychological disorders as classified. The question of how interpersonal change is facilitated during family therapy is of most interest to the practicing family therapist, who is concerned with effective interventions, yet this is the area where there is a relative paucity of research. Thus family therapists tend to seek information on interpersonal change processes from theoretical articles, technical articles, and clinical workshops. This material tends on the whole to focus on what therapists should do, rather than considering what family members themselves need to do. The exception is the work of Kuehl and colleagues, who used ethnographic interviewing procedures in an iterative manner to elucidate accounts of interpersonal change from family members who had undertaken strategic/structural therapy for help with adolescent drug misuse (Kuehl, Newfield, & Joanning, 1990).

It is important to note when reviewing family process studies, that family therapists are challenged by complex demands and intrapersonal and interpersonal tasks during the therapy session that do not occur during individual therapy. For example, the therapist may create interpersonal alliances with family members who may well be in conflict with one another, manages the multiperson conversation in a collaborative and facilitative manner to prevent it becoming destructive, uses family members as "cotherapists," assesses and intervenes in live enactments of problematic family interactions and problem-solving attempts, and so on.

Friedlander, Wildman, Heatherington, and Skowron (1994) reviewed family process research, including naturalistic studies of conjoint therapy in which the focus of the study was verbal behavior of the therapy participants during therapy or their self-reported perceptions of actual interactions during therapy. Thirty-six studies, dating from 1963, met their inclusion criteria. Following Greenberg (1986), they organized their review hierarchically and focused on three levels of in-session behavioral processes: (i) speech acts during therapy, (ii) important incidents or change episodes during therapy, and (iii) the therapeutic relationship. Their review builds on the previous review of family process studies conducted by Gurman, Kniskern, and Pinsof (1986).

The bulk of family process research has been conducted at the speech act level of analysis, where all behaviors occurring during a specified segment of interaction are observed. Frequencies or proportions of these observed behaviors, such as rates of participation, types of response, and modes of expression are compared or otherwise used to predict successful therapy outcome. The following questions have been addressed using speech act analyses: What factors predict premature termination of family therapy? What are the common and distinctive features across different modalities of therapy? What is the relationship between participants' gender and therapy process? What interpersonal changes take place during the course of therapy, and so on. For example, Alexander, Barton, Schiavo, and Parsons (1976) found that the proportion of defensive to supportive speech acts was significantly higher in families who terminated their therapy prematurely. Shields, Sprenkle, and Constantine (1991) compared families who ended therapy prematurely with those who completed therapy in agreement with the therapist. They found that families who ended therapy early were characterized by more in-session disagreements and more attempts to structure the therapist, compared to more family problem-solving conversations and more therapist structuring in response to family disagreements in families who completed therapy. The results suggest that defensiveness amongst family members may predict early termination, although we do not have other information about the families and their contexts, so that the correlations may be misleading. A study by Dowling (1979) examined the consistency of therapist verbal behavior according to their role, therapist versus cotherapist. She found that therapists behaved similarly with different cotherapists and with different families, supporting the notion that therapists had a consistent cotherapy style.

Postner, Guttman, Sigal, Epstein, and Rakoff (1971) investigated family members' verbal behaviors as predictors of outcome. Interactional segments were analyzed at four points in therapy for 11 families. Speech acts were coded into emergency, welfare, or neutral emotional states. Outcomes were coded as good or bad by three independent judges. Results from the good outcomes showed that family members tended to speak more to each other during the course of therapy, that welfare statements increased during the course of the therapy, and that significant changes in emotional expression occurred between the second and sixth sessions. Unfortunately the speech act studies reviewed by Friedlander and her colleagues provide little accumulated knowledge towards answering how change occurs over time during successful therapy. Different investigators have used different coding systems within different theoretical frameworks, thus the generalizability of the findings is limited.

There have been a few attempts to research therapeutic episodes in the hope that by identifying significant moments in therapy, interpersonal change processes will be more readily elucidated. An example is provided in the work of Patterson and Forgatch (1985), who identified and coded instances of maternal "noncompliance." They found that noncompliance responses were more likely to follow therapists' attempts to "teach or confront" mothers, as coded, whereas a decrease in noncompliance was coded following therapists' "support or facilitate" interventions, as coded. Using a larger sample from the same child behavior management project, Patterson and Chamberlain (1988) identified instances of "mother–father within-session conflict" and using path analyses suggested that extraneous forces, such as parental stressors, marital conflict, and depression, appear to increase the within-session conflict among family members. This study is important in elucidating the role of factors outside therapy sessions that have a bearing on behavior in therapy. In addition they found high correlations between in-session conflict and antisocial behavior scores for the children. Patterson and Chamberlain conclude that therapists should plan interventions that help to reduce external parental and marital stressors outside the sessions. The Patterson studies rely on small samples but do provide some interesting support for family systems ideas.

The third level of analysis in the family process studies is the therapeutic relationship itself. Family therapists have not researched the ingredients believed to be important by individual therapists in establishing a therapeutic relationship, such as warmth, empathy, acceptance, and unconditional regard. Instead they have attended to the more strategic and systemic aspects of the therapeutic relationship, such as engaging and joining the family, and the development of therapeutic coalitions. Gurman and Kniskern (1978) concluded that the family therapist's ability to establish a positive therapeutic relationship with family members was most predictive of successful outcome. Since that time very few studies have been conducted and only six met the inclusion criteria of the Friedlander et al. review discussed here. Shapiro (1974) concluded that greater therapist emotional responsiveness to family members, as measured by questionnaire, predicted client continuance in therapy beyond the initial assessment phase. Families who were not seen in such a positive light by their therapists tended not to continue in therapy beyond assessment. These ratings are global with little psychometric support. Later research by Pinsof and Catherall (1986), using a more robust psychometric measure of therapeutic alliances, explored the development of therapeutic alliances across family therapy sessions, and found that such alliances often develop variably rather than uniformly. Their research showed a tendency for positive correlations between alliance ratings and therapist-rated outcomes, with most family members rating their therapist positively, and interestingly, that alliances are best understood as both multidimensional and occurring on multiple levels. Examples are:

whole system alliances, subsystem alliances, and individual alliances.

The study by Kuehl et al. (1990), referred to earlier in this section, will be discussed here because it is an interesting exploration of family members' views of therapy and the change process. Twelve families (37 individuals) who had completed family therapy with successful outcomes for adolescent substance misuse were interviewed. Family members identified stages in the therapy process, collectively described as the introductory meeting, assessment, getting down to basics and generating suggestions, putting suggestions into practice, sharing successes with the counselor, and troubleshooting and follow-up. Satisfaction with the therapy seemed to depend on family members' perceptions of the therapist as caring and understanding and able to generate relevant suggestions, whereas dissatisfaction was reported if the therapist was thought to be on "too strict a program." The flexible use of theory was valued by family members. Where parents reported that they considered their marital problems to be contributing to their child's problem, there was a willingness to explore this connection. Where parents believed their own problems to be separate from those of the adolescent, attempts by the therapist to explore a possible connection was the point at which therapy was reported to "stall."

Friedlander et al. (1994) conclude that most family therapy process studies are descriptive and at the speech act level of therapeutic process. Compared to the wealth of family therapy outcome research, there are few process studies, but a few conclusions are possible. These include: individual symptoms as observed in therapy occur in the context of predictable interpersonal events; there are more commonalities across family therapy approaches than differences, with therapists behaving consistently across family work, central in their position with families and skillful in indirect communications; changes over time in the course of therapy with positive outcomes as affective, cognitive, and behavioral, observed both interpersonally and intrapersonally; affective changes among family members appear to be crucial to effective therapy; family members' responses to their therapists and their therapists' responsiveness to them appear to be important; and finally, family members' motivations to engage in therapeutic activities are predictive of good outcome. More research is needed to address how family members themselves construe therapy and its effective ingredients. Observer ratings represent one possible viewpoint; the covert feelings and thoughts of family members have still to be explored alongside observer ratings. Interpersonal process recall as developed by Elliott (1984) in the context of exploring individual therapy process has promise for exploring family members' perspectives during family therapy. The bulk of the process studies have researched the more established styles and schools of family therapy, with the newer constructivist approaches remaining to be explored. But perhaps the real challenge to family process research lies in developing methods that both avoid isolating behavior from its social context and isolating individual behaviors from the stream of behaviors.

6.04.9 CLINICAL PRACTICE PATTERNS OF FAMILY THERAPISTS

There is little published data on the clinical practice patterns of family therapists, whereas in both the UK and the USA there is a growing body of data on the practitioner demographics and clinical practice patterns of clinical psychologists, psychiatrists, and social workers (VandenBos & Stapp, 1983). Because of the increased interest in family therapy, its effectiveness as a mode of therapy (Pinsof & Wynne, 1995), and the expanding role of family therapists in larger health care teams, Simmons and Doherty (1995) surveyed the clinical practice patterns of marital and family therapists in Minnesota, USA. Marriage and family therapists are currently regulated in 31 states through State and Federal legislation. In the UK registration of family therapists is through the United Kingdom Council for Psychotherapy, and in Europe many countries require the registration of family therapists as specialist psychotherapists.

Simmons and Doherty surveyed American Association for Marriage and Family Therapy (AAMFT) members from Minnesota ($N = 76$) for educational qualifications, demographic characteristics, and practice-related issues. In addition they sought data on 199 treatment cases involving a total of 351 clients, which they claim as a first in the field of marital and family therapy.

Their major findings were that: (i) short-term therapy is practiced, with an average case involving 11 sessions over a four-month period; (ii) therapy with families (average of eight sessions) and couples (average of 10 sessions) is briefer than that with individuals (14 sessions average); and (iii) a wide range of serious problems were treated by the surveyed therapists, including marital problems, depression, anxiety, child problems, and parent–child problems. Although academic training in marital and family therapy seemed to result in a systemic orientation as exemplified by the tendency of respondents to identify family and larger system problems, there was consistency between the respondents and their psychology and social work trained counterparts in the types of client problems treated, the utilization of *DSM* diagnoses, and the lengths of treatment. Simmons and Doherty's overall conclusion was that the clinical practice patterns of marital and family therapists were similar to those of the other established mental health professions.

6.04.10 FAMILY THERAPY AND SYSTEMIC PRACTICE OUTCOME RESEARCH

In both the UK and the USA there is an increased emphasis on the evaluation and audit of clinical practices and outcomes, aimed at the limitation of escalating health care costs whilst improving the quality of care. Family therapists have been collecting outcome data for many years. According to Bergin and Garfield (1994), marital and family therapy approaches have been subjected to rigorous scrutiny, with only a few other forms of psychotherapy studied as often. Different outcome studies have reported the use of single case designs and controlled and uncontrolled group comparison designs. These outcome studies have been reviewed by Hazelrigg, Cooper, and Borduin (1987) and Pinsof and Wynne (1995), and using meta-analytic techniques by Markus, Lange, and Pettigrew (1990) and Shadish, Ragsdale, Glaser, and Montgomery (1995). The overwhelming findings from all these reviews is that family therapy works compared to untreated control groups, with some demonstrated superiority to standard and individual treatments for certain disorders and populations. Meta-analysis demonstrates moderate, statistically significant and often clinically significant effects. The research literature supporting this conclusion is at least as robust as it is for other modes of psychotherapy.

Shadish et al. (1993) conducted a meta-analysis of 163 randomized experimental comparisons of the effects of marital and family therapy (marital = 62; family = 101) with distressed clients, published up to 1988. Seventy-one studies compared marital and family therapy to an untreated control group, and 105 compared it to another kind of marital and family therapy or to another model of psychotherapy. The number is higher than 163 because some studies contained multiple comparisons. The 71 studies showed that therapy clients were better off than the untreated comparison group. The size of this effect was approximately half a standard deviation, which means that the odds of a treated client doing better at post-test than a randomly chosen control client are two out of three. The effect sizes for marital and family therapy were both significant and roughly similar. Comparisons are hard to make because marital and family therapies are offered for the treatment of different presenting problems. The review considered specific presenting problems for the family therapy studies and found that family therapy clients were significantly better off than control clients for general child conduct disorders, child aggression, global family problems, and communication/problem-solving difficulties. Their review included 23 studies that compared marital and family therapies to individual psychotherapies. The differences in outcomes were small and nonsignificant across a range of presenting problems.

Chamberlain and Rosicky (1995), in their review of seven family intervention studies for adolescent conduct disorder and delinquency, published since the Shadish et al. (1993) meta-analysis which included 18 such studies, found that family therapy approaches appeared to decrease adolescent conduct problems and delinquent behavior when compared to individual therapy, treatment as usual, and no therapy, with similar effect sizes of 0.53. Treatment failure in the studies reviewed by Chamberlain and Rosicky correlated highly with poverty and/or social isolation for the family. The Florida Network Study (Nugent, Carpenter, & Parks, 1993) with high risk families found that families who received family therapy were four times as likely to stay together as families who did not, and families who received more than five treatment sessions were twice as likely to stay together as families who did not. So, for these high risk families, family therapy may be a necessary treatment component, but is not sufficient in itself.

Despite the improvements to methodology in the outcome literature, we are still a long way from answering the specific family therapy outcome question posed by Gurman, Kniskern, and Pinsof (1986): "What are the specific effects of specific interventions by specified therapists at specific points in time with particular types of clients with particular presenting problems?" (p. 569).

Gale (1980) provided a series of useful questions to ask when evaluating the quality and character of extant family therapy outcome research, covering issues such as theoretical rational and therapeutic schools, methods of training for therapists, pretreatment characteristics of clients, techniques of treatment, and evaluation of treatment outcome. For example, we might ask:

(i) Who has conducted the research, clinicians or researchers?

(ii) Are the studies well designed and free from bias?

(iii) Are control groups used for different types of family therapy, for family therapy and other forms of psychotherapy, for family therapy and no treatment control?

(iv) Are the effects of the therapist shown independent of the type of treatment?

(v) Are the outcome criteria for success and failure clearly specified?

(vi) Are multiple outcome criteria used and do they intercorrelate?

(vii) Is there a follow-up period and are the effects of treatment persistent over time?

(viii) What characteristics of families/therapists are associated with success and failure?

(ix) Are there nonspecific treatment effects?

(x) What is the comparative cost of family therapy? Is there a cost to the community for failing to provide financial support for family therapy?

Family therapists have a variety of therapeutic approaches to choose from; they are concerned increasingly to provide the best "fit" for clients with their particular circumstances and presenting problems, often without clear evidence supporting one systemic approach over another (Orlinsky, Grawe, & Parks, 1994). When working therapeutically with severe problems, such as adolescent conduct disorder, there is increasing evidence of the value of treatment packages, of which family therapy is a part (Pinsof & Wynne, 1995).

6.04.11 TRAINING AND SUPERVISION

Family therapy training courses at both introductory and qualifying level have been established in the UK since the 1970s, provided by family therapy training institutes. All courses are accredited by the Association for Family Therapy. The criteria for qualifying level training courses include completed training at introductory level, 320 academic hours, and 320 practice hours of which 40 are live supervised, and a personal development component which focuses on family-of-origin experiences and their effects on current thinking and practice.

Many of the qualifying level courses are program-centered (Street, 1988) and concerned to identify theories and skills for systemic practice within their curricula. Thus, the focus of training is very much on the process of teaching. Reviewers of research on family therapy training in both the UK (Street, 1988) and the USA (Liddle, 1991b) have expressed concern at the program-centered nature of the training and questioned to what extent courses address the dilemmas of adult education and adult centered learning, such as exploring the relevance of client change processes in family therapy to family therapy trainees, and learning from the experiences of other psychotherapy training courses. In addition, they point out that courses might do more to close the gap between clinicians and researchers said to exist in the family therapy field, by promoting reflective practice models and qualitative research methodology.

Research into the effectiveness of family therapy training has been limited compared to the proliferation of regulated training courses. Avis and Sprenkle (1990) suggest there are many reasons for this, including the increased complexity of the training issues and their relationship to practitioner outcomes, problems of sampling and replicability, and a lack of reliable and valid measures of training effectiveness. Despite these limitations, Avis and Sprenkle conclude from their review of the training research that conceptual and executive skills may develop at different rates, that different training approaches can bring about similar conceptual and intervention skills developments, that introductory level assessment skills and concepts can be taught using lectures and textbook methods, and that "in-house" training courses for agency staff have been shown to be effective in promoting systemic practices and broadening the remit of mental health services.

Breunlin and his co-workers (1989) attempted to predict which factors might contribute to improved performance in family therapy trainees before and after training on measures of conceptual, executive, and observational skills. Interestingly, previous family therapy experience did not appear significantly to affect change scores, although prior life experience and maturity did seem to be important, but only in changes on measures of executive skills, rather than conceptual and observational skills. Previous experience as an individual psychotherapist predicted improvement on conceptual skills change scores, perhaps suggesting that a previous training prepares trainee family therapists for thinking about therapy processes. Pulleybank and Shapiro (1986) were also interested in the acquisition of cognitive and therapeutic behavior skills during family therapy training. They suggest that their results indicate a developmental progression in learning, with cognitive skills acquired earlier in training, followed by development in planning and then intervention skills. Research by Anderson (1992) raised the knotty problem of how to reconcile differing observer opinions when assessing family therapy trainee performance. Anderson compared the assessments of placement supervisors, academic supervisors, and so-called neutral observers and found more change reported by placement supervisors than the "neutral" observers. The role of evaluation in supervisors' judgments has yet to be systematically researched in the field.

Researchers of family therapy training effectiveness have focused primarily on issues of skills acquisition, theory–practice linking, and preparing trainees for systemic practice outside of the somewhat protected environment of the training course. These issues continue to be of interest and when we map them on to Gurman and Kniskern's (1992) predictions for the future of the field, such as increased diversity of intervention formats and methods, increased recognition of the importance of the relationship between the family therapist and the family members, and increased interest in postmodern developments, the research agenda for training effectiveness into the first decade of the twenty-first century becomes broader.

6.04.12 SYSTEMIC CONSULTATION

Brunning and Huffington (1990) define consultancy as a direct or indirect process enabling individuals, groups, or organizations to fulfill their role, function, or tasks better. It is a process by which the person or persons seeking the consultation ask for help in identifying or clarifying concerns and in considering the options available for problem resolution. Thus, the consultees have legal, ethical, and administrative responsibility for initiative and action, as opposed to supervision where there may well be a hierarchical relationship between the supervisor and the supervisee, or therapy where there is pressure to accept suggestions or directives in order for the therapy to be effective. In the case of family consultation, it may well be a prologue or alternative to family therapy (Street, Downey, & Brazier, 1991). Wynne, McDaniel, and Weber (1986) discuss consultation with families as a process whereby the family members' responsible decision making is assumed and their resources and competence are directly tapped. The decision as to whom to invite to the consultation meetings will depend largely on where the impasse in the system is located. In addition, the systemic view of consultation would see the role of the consultant as a necessary participant in the system requiring consultation.

The stages in the process of systems consultation have been described by Wynne, McDaniel, and Weber (1986) as exploring, contracting, connecting, assessing, implementing, evaluating, and leaving. The stages are not mutually exclusive and represent a process that guides the activity of the consultant. Exploring involves clarifying both the request for consultation and who is requesting the consultation, by considering how the request came about, who approves the request and the role of the consultee in the team or organization requesting the consultation. In particular any political ramifications of the request are explored. Contracting is the process whereby agreement is reached on the goals of the consultation, the services provided by the consultant, consideration of the risks and consequences of the consultation, procedures for sharing information, and other practical arrangements. Connecting is the process of engaging key members of the consultation system in the consultation process and deciding how they will be involved in goal setting. Assessing refers to the methods used for gathering information and the systemic concepts used to understand the organization's structure, function, and dynamics. The assessment process particularly focuses on organizational life cycle issues, recent events triggering the consultation request, previous attempted solutions to the problem, and the belief systems of the consultee. Implementing involves specifying the systemic interventions chosen to meet the consultation request, decisions about whether education is provided, the means of collaborating with the consultee over implementation and procedures to ensure the maintenance of change. Evaluating is the process of deciding how the consultation goals and organizational changes have been met, who will take part in the evaluation process, plans for follow-up evaluation, and reflection on the process of consultation. Leaving describes the means by which a consultation is ended or the consultant renegotiates a different role within the organization.

Campbell (1985) describes an alternative model of systemic consultation specifically designed to help other family therapists who are "stuck" in their clinical work with a family. He adapts the Milan systemic model of family therapy to this task, using theoretical concepts of meaning, pattern, recursiveness, and difference. The consultation interview follows a similar procedure to a Milan-style family therapy interview with presession hypothesizing based on preliminary information, the use of circular questioning and reframing, characterized by the neutral stance of the therapist, and midsession breaks for team discussion and final formulation. The main aim of this style of consultation is to provide a space to comment on and clarify some of the confusions that arise when working in systems where different meanings for behavior arise from the differing perspectives from which that behavior is viewed.

In summary, systems consultation has the advantages of not prejudging the nature of the problem requiring consultation; the consultant can take a meta position from which to develop a perspective on systemic relationships and patterns; the consultation process facilitates the reframing of problems and the search for competence and strengths; a more collaborative relationship between consultant and consultee can be established because the consultee is "free" to take the advice offered or not; and the role of consultant does not preclude a shift to an alternative role, such as therapist.

6.04.13 CONCLUSION AND THE WAY FORWARD

Looking ahead to the next millennium is both exhilarating and daunting. The development of family therapy and systemic approaches to practice has been rapid, encapsulating and condensing the natural history of the development of systems of thought and professional disciplines. A time for consolidation of practice and ideas would be welcome. Rapprochement with other psychotherapies proceeds apace. The emphasis on context as an infinitely layered and dynamic process has enormous implications beyond the practice of family and systemic therapies. An ecosystemic vision and practice awaits us all.

6.05.1 THE ORIGINS OF PSYCHODYNAMIC THERAPY

6.05.1.1 Definition of Psychodynamic Therapy

The term "psychodynamic psychotherapy" covers a somewhat heterogeneous range of psychological interventions which draw their inspiration from psychoanalytic theory. Various implementations of this form of treatment (see Chapter 14, Volume 1) emphasize different aspects of this rich body of ideas including: (i) notions of psychic conflict as an all-pervasive aspect of human experience; (ii) the internal organization of the mind to avoid unpleasure arising out of conflict and maximize a sense of the experience of safety; (iii) the use of defensive strategies for the adaptive manipulation of ideas and experience to minimize unpleasure; (iv) a developmental view of psychopathology as arising out of the long-term adverse consequences of adaptations at earlier phases of development; (v) the organization of experience in terms of the internal representations of relationships between self and other throughout the life span; and (vi) the expectable re-emergence of these experiences in the relationship with the therapist. Psychodynamic therapies are predominantly verbal and interpretive aimed at the modifications of restructuring of the representations of relationships primarily, but not exclusively, through the use of insight.

6.05.1.2 The Short-term Emphasis in Psychodynamic Therapy

Psychodynamic psychotherapies are rooted in long-term, time-unlimited approaches, and many of the most important advances in theory and technique originate from this context. The emphasis in the present chapter will, however, be on short-term psychodynamic approaches. The rationale for this emphasis may be stated as follows: The demand for psychotherapeutic treatment as either an adjunct to pharmacotherapy or as a unique treatment is considerable and has increased substantially over recent years as a function of cultural, social, and economic changes (e.g., lessened stigma attached to seeking assistance with psychological problems, increase in some risk factors for mental illness such as drug and alcohol use) and the greater availability of providers (Howard et al., 1996).

Surveys of the delivery of psychotherapy in both public and private health care settings demonstrate that the majority of clients receive relatively short-term treatment. The majority of patients receive less than 10 sessions (DeLeon, VandenBos, & Bulatao, 1991; Olfson & Pincus, 1994), although therapists spend the majority of their time with the relatively small proportion (15–20%) who attend more than 26 sessions (Howard, Davidson, O'Mahoney, Orlinsky, & Brown, 1991; Taube, Kessler, & Feuerberg, 1984) and thus may come to believe that long-term treatment is more common than it actually is. It should be remembered however that estimates of the mean length of treatment for psychotherapy are reduced by the contribution that general (primary care) physicians make to this type of mental health care provision (approximately 30%), the majority of whom provide extremely brief forms of treatment (one to three sessions) (Olfson & Pincus, 1994; Olfson, Pincus, & Dial, 1994).

Managed care, with its declared intention of cost containment for health care provision, requires a more structured, focused, treatment-goal-oriented psychotherapeutic approach (Brosowski, 1995; Richardson & Austad, 1991). There has been a shift in the formulation of the nature of both psychological disorder and interventions aimed to address it from an acute to a chronic illness model: certain individuals are seen as requiring therapeutic input, briefly, but repeatedly, throughout the life cycle, especially in relation to life crises (Cummings, 1988; Kazdin, 1988; Roth & Fonagy, 1996).

6.05.2 TECHNICAL ISSUES IN PSYCHODYNAMIC THERAPY

6.05.2.1 Suitability for Psychodynamic Therapy

Whereas medical treatments tend to have clear indications and contraindications for specific interventions, the emphasis of assessment for psychodynamic therapy tends to emphasize the looser notion of general "suitability" (Tyson & Sandler, 1971). Nevertheless, some writers have made specific recommendations concerning suitability for long-term (e.g., Coltart, 1988) and short-term therapy (e.g., Malan, 1980). While some authors have suggested relatively systematic assessment, which yields both diagnostic and prognostic features (e.g., Kernberg, 1981), in terms of the developmental level of the patient's personality organization most psychodynamic clinicians rely on clinical judgments based on interpersonal aspects of their first meeting with the patient (Etchegoyen, 1991). The three areas of greatest relevance to suitability are: patients' personal history, content of the interview, and style of presentation.

In terms of the patient's history, good evidence of personal achievement and at least one good relationship has been traditionally regarded as a good prognostic indicator (Malan, 1980). A history of psychotic breakdown, severe obsessional states, somatization, and a lack of frustration tolerance are normally regarded as contraindications. There are many psychodynamic clinicians who report working successfully with patients who in the past had been regarded as unsuitable because of their histories: for example, psychotic (Rosenfeld, 1952), learning disabled (Sinason, 1992), and chronically poorly controlled diabetic individuals (Moran, Fonagy, Kurtz, Bolton, & Brook, 1991). Psychodynamic clinicians treating clients in long-term psychotherapy, particularly those working intensively, are more likely to make such risky selections.

There is even less agreement about suitability concerning the content of assessment interviews. In general, clinicians tend to make their judgment on the basis of the presence of a "mutuality" between them and the patient and observed responses to "trial interpretations" in which they attempt to summarize their initial impressions concerning the patients' presenting problem in the context of their current and past life situation (see below). In addition, therapists may try to identify if the patient has the capacity to respond emotionally within the sessions to allow feelings of fear, sadness, or anger to come to the surface (Orlinsky, Grawe, & Parks, 1994). Some clinicians, though by no means all, attempt to assess the patient's motivation for treatment. This is, however, hard to do as superficial expression of commitment may or may not predict the willingness to confront unpleasant aspects of oneself. For this reason it is probably impossible to obtain genuinely informed consent in psychodynamic psychotherapy research.

More recently, psychodynamic therapists have paid more attention to the nature of the patient's discourse rather than just its content. Holmes (1995), for example, observes if the patient's narrative styles are markedly avoidant and dismissing of interpersonal issues or appear entangled and enmeshed with them with much current anger about past hurts and insults. There is at least one study that shows that the former type of patient has a somewhat better prognosis in psychodynamic therapy (Fonagy et al., 1996). Patients' narrative style may also be a clue to the extent of their reflectiveness: the capacity to see oneself from the outside (Sandler, Dare, & Holder, 1992), autobiographical competence (Holmes, 1992), the ability to reflect on one's inner world (Coltart, 1988), and fluidity of thought (Limentani, 1972) are all considered indicators of suitability.

6.05.2.2 Formulation of Patients' Problems

Psychodynamic theory is too diverse to permit definitive formulations. Formulations identify central unconscious conflicts, maladaptive defenses, unhelpful unconscious fantasies and expectations, deficits in personality development and the like. Formulation depends on the theoretical orientation of the psychodynamic clinician. In Chapter 14, Volume 1 of this work we have reviewed the range of currently popular orientations. Agreements, however, are hard to reach even when clinicians follow the same orientation (Horowitz, Rosenberg, Ureño, Kalehzan, & O'Halloran, 1989). Some standardized approaches have, however, been developed (Perry, Cooper, & Michels, 1987; Perry, Luborsky, Silberschatz, & Popp, 1989).

While there is no generally accepted schema for formulations, there are several key parameters that clinicians generally consider. These are: (i) the extent to which representations of relationships are mature, that is, involve three or more persons rather than just a two-person, self–other dimension (Karasu, 1990); (ii) the quality of psychic defenses, particularly the predominance of primitive defenses rather than more mature ones (Vaillant, 1992, and see below); (iii) the extent of whole, as opposed to part object relations (where individuals are represented as whole persons rather than just an aspect or a function of a person, e.g., feeding or nurturance, sexual gratification, a container for evacuation) (Kernberg, 1984).

Considerations such as these usually serve two functions. The first of these is to suggest the likely effectiveness of the type of treatment: short vs. long-term, intensive vs. nonintensive psychodynamic therapy. On the whole, patients seen as more severe on parameters such as the three suggested above are less likely to do well according to most studies of psychodynamic treatment (e.g., Wallerstein, 1986). The second function of formulations is to give an initial focus to the clinical work, which in the case of brief therapy may be the sole focus of the treatment. In long-term therapy these formulations tend to change, sometimes radically, on the basis of information emerging in the course of treatment. Winnicott (1965) referred to psychodynamic treatment as "an extended form of history taking."

6.05.2.3 Mechanisms of Defense

6.05.2.3.1 The concept of defense in various theoretical frameworks

Within classical theory, which sees conflict as the core of mental function (e.g., Brenner, 1982), defenses are seen as adaptations to intrapsychic conflict. Within object relations theories, defenses are seen as assisting the individual to maintain an authentic self-representation, a true (Winnicott, 1965) or nuclear (Kohut, 1984) self. Within attachment theory, defenses are seen as maintaining desirable relationships (Holmes, 1993). Within a Klein–Bion frame of reference, defenses are often conceived of in terms of complex structures or systems called organizations. The term underscores the relative inflexibility of some defensive structures. Personality types appear to be characterized by specific types of defensive organizations. For example, in narcissistic disorders idealization and destructiveness, the devaluation of genuine love and truth, may have been protective at one developmental stage but came to acquire a stability which seems to be based on the emotional pay-off from this form of adaptation (Rosenfeld, 1964, 1971; Steiner, 1982).

6.05.2.3.2 Primitive defenses

Regardless of theoretical orientation, there is general agreement about common forms of defense and their relative sophistication from a developmental standpoint (Vaillant, 1992). The primitive defenses tend to be found together in certain individuals. Borderline individuals, who idealize and then derogate their therapists in order to maintain their self-esteem, are using splitting and projection. Projective identification (Klein, 1946) is also common in this group. Projection, the simple ascribing of an undesirable mental state to the other, becomes a more powerful mechanism when the other can be unconsciously forced to accept the projection and experience its impact, thus the "identification" is in the recipient of the projection. This current interpretation of the term is particularly well described by Ogden (1979). It clearly goes beyond Klein's original meaning: the patient fantasizing that the recipient of the projection acquired a part of the patient's self. Spillius (1994) suggests a helpful clarification; she calls projective identification which invites the therapist to actualize the projection, "evocative projective identifications."

Either in fantasy or in actualized form, projective identification offers a primitive method of experiencing control over the other within a relationship (therapeutic or care-giving) (Bion, 1955). When parts of the self are experienced as being within another person, the individual frequently makes attempts to control these split-off parts by exerting total control over the recipient or container of the projection. Bion (1962) also stresses that good, as well as undesirable, aspects of the self may be externalized via this route, making projective identification one of the principle avenues for communication in infancy. Other functions of projective identification, beyond communication and control, include: the acquisition of the object's attributes in fantasy, the protection of a good quality from internal persecution by evacuating it into an object, and the avoiding or denying of separateness. It is thus a fundamental aspect of an interpersonal relationship focused on fantasy, and its appreciation is critical for adequate psychodynamic psychotherapeutic practice.

6.05.2.3.3 Neurotic and mature defenses

Anna Freud (1936) is to be credited for the delineation of most of the mechanisms of defense commonly used in clinical formulations today. It is not possible to give detailed consideration to each of these and most are, by now, part of common parlance (and exist as terms of mild rebuke, at least between mental health professionals). Defenses involving access to mental representations (e.g., repression) or the attribution of emotional significance to these (e.g., denial or disavowal) are perhaps most commonly encountered as part of individual coping strategies. For example, jokes containing emotionally threatening, sexual, and aggressive material are notoriously hard to remember. Denial of the emotional significance of incurable disease may be helpful in increasing the patient's chance of survival (Greer, Morris, & Pettingale, 1979). Turning a response into its opposite—terror into aggression (reaction formation)—is particularly common in children in response to abuse, and identification with the aggressor (becoming the tormentor instead of the victim) is common amongst maltreated children who become abusers in adulthood (Oliver, 1993). Other commonly noted neurotic defenses include: undoing (performing a magical reparative act), intellectualization and rationalization, and humor.

The diagnostic significance of mechanisms of defense is controversial. Some workers claim predictive specificity for such assessments beyond that of psychiatric diagnosis (Perry et al., 1989; Vaillant, 1992). The theoretical ambiguity which surrounds the concept makes its widespread use as a diagnostic device unlikely, at least in the short term. Its inclusion in this chapter is justified by its heuristic value: conceptualizing patients' reactions in terms of defenses makes psychodynamic work practicable. All of these defenses are common reactions in psychodynamic therapy, particularly at times of emotionally challenging work. Recognizing them has to become part of the working routine of the psychotherapist. For example, the forgetting of material from last week's session is more common than remembering it, even amongst people whose memory for other, far more trivial, aspects of their daily life is nothing short of admirable. The psychotherapist recognizes the patient's defenses and mostly uses them as an indication of the presence of underlying anxiety rather than as occasion for confrontation (but see some brief therapeutic strategies below).

6.05.2.4 The Context of Psychotherapy

6.05.2.4.1 The therapeutic contract

Although contracts are far more relevant for short-term than for long-term therapy, most psychodynamic therapists explicitly or implicitly convey objectives and expectations to their clients. The details of the agreement usually include time and place, the length and frequency of sessions and an initial idea concerning the likely duration of therapy, the expected behavior of the patient and the therapist and so on. It is the emotional context of this agreement that is often more important than the items which it includes. It implies a mutual recognition by both parties of the importance placed upon protecting the process of therapy.

6.05.2.4.2 Abstinence and neutrality

Freud (1915) originally wrote about the analyst resisting the temptation of gratifying the patient's sexual desires. Although this is clearly an ethical issue, it also pertains to analysts forgoing gratifying patients' curiosity, or using patients to gratify their own personal needs. Equally, the patient undertakes to forgo major life changes where these are currently the subject of psychotherapeutic attention. Whereas this is particularly important in short-term treatment, even long-term psychodynamic treatment can flounder if the emotional experiences of the therapy are obscured by the upheavals from major life events.

Abstinence ensures therapeutic neutrality. Psychodynamic therapists go to great lengths not to direct their patients' associations and remain neutral no matter what the content of the patients' past experiences or fantasies may be. Although this is frequently caricatured, it is important for the psychodynamic therapist to retain a certain emotional distance from the client, sufficient for the latter's fantasies and hidden fears to emerge. Needless to say, neutrality must be balanced by sensitivity. The recent literature on the working alliance (see below) underscores that the therapist's genuine concern for the client must come through if significant progress is to be made.

6.05.2.4.3 Regression

One aim of psychodynamic psychotherapy is to activate and explore aspects of personality functioning which are normally obscured behind the patient's need to adapt to the demands of everyday reality. Psychodynamic therapy, to a degree, encourages access to these representations through the process of regression. This is less of an active encouragement than a passive permission. Sandler and Sandler (1994) suggested that an "antiregressive function" is normally active in all of us, and psychotherapy can function as a way of disinhibiting this function in much the same way as intimate interpersonal and certain types of large group situations and alcohol appear to do. Some therapists consider regression to be an essential part of successful treatment (Balint, 1949; Winnicott, 1971). Certainly the fear of regression can become an important source of resistance (Sandler & Sandler, 1994).

6.05.2.4.4 Resistance

Resistance is an essential component of psychodynamic treatment. The word dynamic implies the presence of forces rallied against change. Resistance, like regression, fluctuates in intensity across treatment and may serve different functions at different times and in different individuals. In narcissistic and borderline states, resistance may protect the patient's self-esteem (Kernberg, 1988; Kohut, 1984); in more neurotic cases it may focus around preventing the integration of experience (Thomä & Kächele, 1987).

It may also take different forms. Clients access to their mental life (e.g., remembering dreams) may be experienced as restricted (repression resistance). Others may wish to keep their relationship with their therapist at an extremely superficial level (transference resistance). Some patients show a paradoxical reaction to their treatment: The better it progresses the worse they feel (e.g., new symptoms emerge). Freud (1923) attributed this to unconscious guilt. In some patients, at least, it is more likely to be linked to their pervasive predisposition (envy) to destroy all things in their life which they experience as good but beyond their immediate control (Kernberg, 1975; Rosenfeld, 1975).

6.05.2.5 Transference

6.05.2.5.1 The history of the concept

The concept of transference originated with resistance. In his work with the cathartic method (Breuer & Freud, 1895) Freud initially understood the patient's intense emotional reaction to the therapist as an interference with what was an essentially verbal method. He quickly realized that the patient's emotional experiences could be better understood as representations of earlier relationship experiences (particularly Oedipal strivings and disappointments) which could be understood in terms of past experience and in fact made that experience emotionally more meaningful for the patient (Freud, 1914).

6.05.2.5.2 The origin of the transference experience

The patient's intense feelings of anger, suspicion, and disappointment, or love, admiration, and excitement about the person of the therapist are unlikely to be a realistic response, since two patients may experience such opposite feelings towards the same therapist at similar times. There are currently a range of views about the origin of transference experiences. Some believe that transference is based on actual past experience: the expression of expectations based on past experiences of relationships (Bowlby, 1980). In this view, transference distorts the actual relationship; patients see what they expect to see and resist understanding by repeating past relationships in a rigid manner (Levenson, 1983). There is an implication in this view of a "correspondence" between present and past. Many therapists are reluctant to accept the idea of such a direct relationship. For them transference is an aspect of the patient's narrative; it gives "coherence" to the patient's experience of the therapeutic relationship, but it is not an expression of an underlying truth about the patient's history (Gill, 1982; Spence, 1982). Transference is constructed in the present and cannot give us clues to the past. By contrast, some who work within a Klein–Bion perspective see transference as a unique window to the patient's current internal reality (e.g., Joseph, 1986). For example, confronted with an idealized transference they might see the patient's true state as organized around psychotic anxieties related to the death instinct. The idealization is a desperate defense against the destruction which they fantasize may engulf both them and the therapist. Cavell (1994) demonstrated that the dialectic between these conceptions of the transference has important philosophical roots in the debate between "correspondence" and "coherence" models of truth.

Additional suggestions by object relations theorists have in some ways complicated the issue. Here transference is based neither on expectations, defenses against expectations, nor constructions aimed to achieve coherence, but rather on a process of externalization of internal objects (Kernberg, 1984). Such representations cannot be seen as true or false; they are distorted by fantasy and defensive processes.

6.05.2.5.3 The limits of transference interpretations

There is a further important debate with regard to the relevance of a transference focus in psychodynamic therapy. Some therapists are inclined to see transference as covering all aspects of the analytic situation. Joseph, (1986) for example, sees the total situation in the therapy as reflecting an internal state of affairs in the patient's mind. Thus other aspects of the therapeutic relationship, for example, the so-called alliance and the so-called real relationship, are all subsumed under the transference. By contrast, Strachey (1934) conceived of transference as externalization of the patient's superego. The therapist, unlike other people in the patient's life, does not accept this externalization, be it idealized, denigrated, or judgmental, and conveys his or her understanding of it by so-called "mutative interpretations." This view implies that the only truly therapeutic interpretations are those which involve the transference, but clearly admits of other aspects of the relationship. Other therapists, particularly in the Freudian school (e.g., Anna Freud, 1936), see transference interpretations as just one category of interpretive intervention and give them relatively little particular priority.

6.05.2.5.4 Special forms of transference

There are several psychodynamic observations concerning special forms of transference which are helpful to particular groups of patients. Kohut (1984) described some common transference patterns with narcissistic patients. Individuals whose self-objects (parents) failed in their mirroring function may continue to crave for approbation and admiration and manifest this pattern in therapy. This is termed the mirroring transference, which Kohut recommends the therapist should not puncture by premature interpretations. Idealizing transference similarly aims to meet defective self-esteem by vicariously identifying with the perfect therapist. It is a highly controversial recommendation of Kohut's for therapists to accept such transferences. On the one hand, behind such exaggerated accolades may lie deep frustration and even rage; on the other, if Kohut is correct, destroying this image of the therapist is tantamount to a destruction of the patient's self-regard.

Erotic transference is also thought to have infantile roots and occurs relatively commonly in therapeutic relationships, whatever the gender of the therapist and the patient. It tends to be highly embarrassing for the patient and sometimes also for the therapist. Most agree that it is a distraction and some suggest that it is a manifestation of a defense against either recognizing damage done to the object or the fragmented state of the self (e.g., Steiner, 1982). Alternatively, from an attachment theory perspective, erotic transference may be a way of forcing the unresponsive object to pay attention. At the extreme end of this dimension is erotized transference where the demand for sexual gratification is not experienced by the patient as unrealistic (Etchegoyen, 1991). Such reactions are particularly common in severely traumatized individuals.

6.05.2.6 Counter-transference

6.05.2.6.1 History of the concept

Counter-transference in its broadest sense refers to the thoughts and feelings of the therapist during a treatment session which are in some ways relevant to the patient's current experience and thus may be involved in illuminating the patient's reaction or, indeed, obscuring it. Langs (1976) usefully distinguished between counter-transferences which may be attributed to the patient and those which result from the analyst's neurotic reaction to some aspect of the therapeutic situation.

The concept of counter-transference, like that of transference, is rooted in the notion of resistance. Freud, throughout his career, never recognized the value of counter-transference as an indicator of the patient's subjective state (Freud, 1912). Heimann (1950) expanded the usefulness of the concept by pointing out that the therapist's feelings and thoughts about the patient's communications, if reflected upon, could provide important clues about the patient's current state of mind. The idea was controversial (e.g., Fliess, 1953) yet it gradually gained acceptance. Those psychotherapists who were committed to an interpersonalist tradition (e.g., Sullivan, 1953), and saw the relationship aspect of psychotherapy as its most important facet, welcomed this expansion of the counter-transference concept. From their point of view the omniscient neutral analyst was an anachronistic anathema; accepting the analyst's human reaction was a welcome democratic humanistic development (Abend, 1989).

6.05.2.6.2 Types of counter-transference

Racker (1968) distinguished between complementary and concordant counter-transference. Concordant counter-transferences are based upon primitive empathic processes within the therapist. The latter resonates with as yet unverbalized experiences of the patient. Complementary counter-transferences arise when the patient treats the analyst in a manner congruent with an earlier relationship pattern. King's (1978) notion of "reverse transference," where patients treat the therapist as they felt treated when children, is a special instance of this category.

The case of concordant counter-transference particularly raises the issue of the mechanisms by which analysts may become aware of the patient's unconscious experience. Sandler (1993) offers the notion of "primary identification" as a rapid process of automatically mirroring one's partner in a communication and only becoming aware of this upon reflection. There is good evidence for such a process, particularly in the infant development literature (Osofsky, 1995).

Only when such primary identifications touch on unconscious conflicts within the analyst, with a consequent mobilization of defensive processes, will counter-transference start to be a distorting process. Grinberg (1962) pointed out that such experiences could lead therapists to withdraw from the therapeutic relationship. Therapists sensitive to, and resonating with, feelings of inadequacy in patients may be made anxious by such feelings and become defensively angry or hypermotivated to show their effectiveness. To some degree this may be an inevitable part of the process with the therapists only gradually understanding the reasons behind their unusually defensive style of relating. Bion (1962) stressed the importance of the recipient of the projection (the container) being able to "metabolize" and feed back the products of such primitive communications. Sandler (1976b) pointed out that therapists needed to allow themselves sufficient freedom of action to be able first to enact the patient's projection and then respond to the enactment in appropriate ways. Along similar lines, Brenman-Pick (1985) cautioned that the therapists' psychopathology frequently required that they worked through counter-transference identifications so that their wish not to know was turned into a potential for knowing.

Not all counter-transference reactions are provoked by patients' projections or reactions to the anxieties that these create. Winnicott (1949) was perhaps the first to point out that the outrageous provocative behavior of certain borderline or psychotic patients produced a normal reaction of "objective hate." Kernberg (1984) formalized this, suggesting that such behaviors activated primitive aspects of the therapist's personality. Understanding these reactions naturally helps the therapist empathize but it is neither a complementary nor concordant reaction, nor is it a defense against affective resonance. It is simply one further indication that the therapist too is human.

6.05.2.6.3 Counter-transference and interpersonal approaches

Modern psychodynamic theory considers counter-transference as firmly located in the interpersonal field. The patient and psychotherapist are seen as two mutually influencing psychological systems (Langs, 1978). Both transference and counter-transference are seen as the product of a subtle interplay between conscious and unconscious systems of both patient and analyst. Influences occur in both directions at both conscious and unconscious levels (Arlow, 1993). Some writers go so far as to suggest that patient and therapist share an unconscious fantasy of creating an intersubjective field between them (Baranger, 1993). Whether correct or not, these modern approaches emphasize that it is no longer possible to consider the therapist's role as "neutral" or "mirror-like" and that the psychotherapeutic process is a highly subjective admixture of a range of complementary processes that establish themselves in a unique configuration for each therapy.

6.05.2.7 Therapeutic Interventions

6.05.2.7.1 Historical overview

There has been a dialectic throughout the history of psychodynamic approaches between orientations that emphasize insight and interpretation and those that stress the unique emotional relationship with the therapist as the primary vehicle of change. The controversy dates back to the earliest days of psychoanalysis, to Freud and Ferenczi, but re-emerged powerfully with first the work of Balint and Winnicott set against classical Freudian and Kleinian theorists, and later Kohut and self psychology opposing the classical ego psychology tradition. This dichotomy is clearly artificial, as it is hard to envision effective psychodynamic therapy without both components (see Wallerstein, 1992). It is nonetheless helpful in presenting the range of techniques used by most psychodynamic therapists which span the spectrum between emotional relationship-oriented techniques and insight-oriented ones. Winnicott (1971) referred to this dimension as "being with" versus "doing to." As supportive interventions tend to suggest particular lines of association, an overlapping dichotomy exists between the use of directive and nondirective techniques.

6.05.2.7.2 Supportive and directive aspects of psychodynamic interventions

There are a whole range of supportive techniques used more or less deliberately by psychodynamic psychotherapists. These include: explicit support and affirmation; concern and sympathy (e.g., in response to bereavement or major setback); reassurance, commonly concerning irrational anxieties about the therapeutic arrangements; empathy with the patients' painful internal struggles, and so on. The complexity of such interventions was well illustrated by Feldman (1993). He showed how patients may experience the therapist's submission to a demand for reassurance as anxiety provoking rather than calming, since they may be unconsciously aware that the therapist's genuine position is incompatible with offering such palliatives and are thus faced with the deep fears concerning their own omnipotence and the therapist's weakness. Nevertheless, Kohut's (1984) emphasis on empathy was undoubtedly a welcome counterbalance to the rigid interpretive techniques of many classical ego psychologists and seems appropriate with patients who have experienced little genuine concern in their history.

Psychodynamic therapists are most likely to use supportive and directive techniques which encourage the therapeutic process. Elaborative techniques, such as "Tell me more about that," undoubtedly direct the patient's attention to specific issues and focus the treatment but may be essential precursors to interpretive work proper. Clarification is also a commonly used technique which involves a restatement of the patient's utterance or just offering a label (a symbol) for an internal state which the patient has limited capacity to represent. Clarifications shade into interpretations and the distinction is hard to draw in actual practice. Confrontation is a subtype of elaboration and clarification. The therapist, having identified inconsistency, brings this to the attention of the patient, usually in a supportive but firm manner (e.g., drawing the patient's attention to the absence of affect appropriate to a specific situation).

6.05.2.7.3 Interpretation in psychodynamic therapy

Interpretation is the paradigmatic intervention. Perhaps not surprisingly therefore it is often idealized as the sole or uniquely effective method for bringing about psychic change. Menninger (1958) offered a useful classification for psychodynamic interpretation. He suggested that interpretations addressed principally one of three aspects of a conflict: the defense, the anxiety, or the underlying wish or feeling. The content of the interpretation could be further subdivided as concerning current external reality, the transference, and childhood relationships.

The phase of the treatment is most likely to determine the therapist's choice. Commonly interpretations move from current events through the transference to the distant past. Similarly, generally interpretations start with the anxiety, through the identification of the defense to accessing the repudiated affects. In practice, neither of these patterns can be considered more than a guideline to be loosely applied. For example, very long-term therapy often ends up focusing on supportive exploration of current events (Blum, 1989). This is not surprising since the distant past can only be worked over a limited number of times. Similarly, defenses, if interpreted without regard to the anxiety, may well come across as implicit criticisms of the patient. Yet early interpretations of an unconscious wish can be puzzling and confusing even for relatively intact patients. Furthermore, severely personality disordered individuals respond poorly to interpretations of the distant past. Their reality testing may be too tenuous and they may overattribute their current experience to past events. It is clearly preferable to work with such patients uniquely in the here and now if gross distortions of history are to be avoided.

(i) Transference interpretations

Strachey (1934) placed transference interpretation at the center of psychodynamic work. As discussed above, his rationale for this was constructed as a route out of a vicious cycle of the external confirmation of the patient's repudiation of certain fantasies and feelings. Others, however, saw different strengths in "working in the transference." A focus on the therapeutic relationship offers the patient the opportunity to internalize the thinking function of the therapist (Hoffer, 1950), the relationship with the analyst as a new object (Klauber, 1972), the therapist as a self-object (Kohut, 1977; Kohut & Wolf, 1978), or adopt a pretend stance facilitative of the development of an awareness of other minds (Fonagy, 1991, 1995).

Steiner (1993) pointed to this latter aspect of interpretations when he distinguished "analyst-centered" and "patient-centered" aspects of interpretations. When therapists interpret what they imagine to be going on in the patient's mind they make patient-centered interpretations; when they interpret the patient's reactions in terms of what they imagine the patient is thinking about what the therapist is thinking or feeling then this is an analyst-centered interpretation. Here the patient is directly learning about how minds interact within social relationships (Fonagy, Moran, & Target, 1993). Whereas the former type of interpretations, if used to excess, may appear to be blaming the patient, the latter type make the therapists appear as if their concerns were purely narcissistic and not sympathetic to the patients' real difficulties in the external world.

(ii) Extratransference interpretations

Most psychodynamic clinicians now agree that a balance needs to be struck between transference and extratransference interpretations (Stewart, 1989). O'Shaughnessy (1992) evocatively described how a treatment focused too much within the transference can become "an over-close enclave" and extratransference interpretations had the power to break the claustrophobic atmosphere. Sometimes, the spontaneous and direct communication of the analyst's experience of frustration ("objective hate") may help the patient see the therapist as a real person and break a repetitive unproductive pattern in the therapy (Coltart, 1986; Symington, 1983). Kernberg (1995) is probably accurate in saying that patients in the borderline spectrum benefit specifically from well-structured, here-and-now transference interpretations.

6.05.2.8 The Result of Psychodynamic Interventions

6.05.2.8.1 The role of insight

Just as interpretation is paradigmatic but by no means the sole effective component of psychodynamic interventions, so insight may be an oft idealized but, in reality, relatively rare outcome of therapeutic work. Insight is the conscious recognition of the role of unconscious factors (feelings, experiences, fantasies) on current experience and behavior. "True insight" and mere and intellectual knowledge should be carefully distinguished (Zilboorg, 1952). Thomä and Kächele (1987) identify insight as equidistant between the poles of pure intellect and simple emotional experience. Etchegoyen (1991) helpfully distinguished between descriptive or verbal insights on the one hand and ostensive or shown insights on the other. The latter is a more direct form of knowing and pertains to the common experience when one is in emotional contact with an event one has known before.

There is general agreement that insight is an integrative experience (Thomä & Kächele, 1987). Those who follow a Klein–Bion model would describe this as a healing of defensively instituted splits in the patient's mental representations of others and their relationships to them (e.g., Segal, 1962). In more general terms, it may be seen as an instance of a more general predisposition to think in terms of the mental states of one's objects and understand one's relation to them in mental state terms (Fonagy & Target, 1996). This tendency may also be described in terms of a willingness to see the interpersonal world from a "third-person perspective" (Britton, 1989, 1992).

6.05.2.8.2 The role of working through

Neither intellectual nor emotional insight is sufficient for progress (Freud, 1914). The function of working through is to help the patient to practice a newly arrived-at integration. This has two components: first, to unlearn the implications of prior misconceptions, and second to assimilate, and practice working with, new constructions. It is interesting to note that the literature on long-term therapy pays far less attention to this aspect of the outcome of interventions than the process of interpretation which merely is the starting point of the change process. Short-term therapies necessarily pay far more attention to the need to present and re-present psychotherapeutic understanding. The relative effectiveness of short-term interventions may owe much of their potency to the systematic way in which the task of working through is tackled (see below).

6.05.2.9 Ending Treatment

6.05.2.9.1 Indications for ending treatment

Like much of psychoanalytic psychotherapy, the ending of treatment is often idealized. The desirable final outcome is often stated in terms of the process of treatment. Kennedy and Moran (1991), following Anna Freud , helpfully separate the process aims from the outcome aims of psychodynamic treatment. The former is likely to be stated in theoretical terms (e.g., a move from paranoid to depressive anxieties, an increase in the coherence of the patient's narrative, an increased awareness of impulses and fantasies, a manifestation of genuine concern for others and so on). All these are observed in the context of the treatment and are at best loosely coupled with the goals the patient might have for ending the treatment.

The latter are often external changes such as the decline of symptoms, improvement of relationships, decrease of unpleasant affect, an increased capacity for assertiveness, and so on. These external criteria are sadly regarded by many psychodynamic clinicians as superficial as they can be achieved without fulfilling the process aims of the treatment (Grünbaum, 1984). Evidence will have to be gathered which clearly demonstrates that external change associated with process change is more extensive or longer lasting than external changes achieved in isolation.

6.05.2.9.2 The process of ending treatment

There is general agreement that ending treatment is "a process." Different authors identify different processes: a new beginning (Balint, 1949), weaning (Meltzer, 1967), mourning (Klein, 1950), detachment (Etchegoyen, 1991), and maturation (Payne, 1950). An inevitable part of ending is disillusionment with not having achieved the ideal (Pedder, 1988), and the loss of the object who has been the receptacle for projections (Steiner, 1993). As part of this process, symptoms might return, if briefly, and problems already worked through may appear to resurface. Most clinicians agree that other than acknowledging the unconscious issues around ending, no specific technical maneuvers are indicated.

6.05.3 ILLUSTRATION OF LONG-TERM PSYCHODYNAMIC THERAPY: PSYCHOTHERAPY FOR BORDERLINE PERSONALITY DISORDER

6.05.3.1 Theoretical Approaches to Borderline Conditions

Psychodynamic theories of borderline personality disorder (BPD) are discussed extensively in Chapter 14, Volume 1 and only a brief summary of these views will be presented here. Broadly there are two approaches to understanding this relatively rare but troublesome disorder characterized by intense but unstable personal relationships, self-destructiveness, impulsivity, poor social adaptation, self-damaging behavior or suicidality, chronic dysphoria, transient psychotic episodes, and so on. There are those who suggest conflict as the central theme and those who favor an explanation in terms of deficit.

The conflict model is best represented by the Klein–Bion tradition (e.g., Steiner, 1993) as well as by the work of Kernberg (1984). A key feature of these formulations is the unsuccessful integration of good and bad part-objects, and the use of primitive defenses (particularly projective identification and idealization and derogation). It is assumed that children cannot deal with excessive aggression arising from abandonment experiences and are forced to split again and again their internal representations to protect their internal sense of good. By contrast, deficit models ascribe the internal fragmentation of borderline patients to deprivation experiences which leave the ego weak and unable to self-soothe. Consequently such individuals draw on exogenous stimuli such as drugs, binge eating, or self-harm to induce mood states (Adler, 1985). Narcissistic features which accompany borderline states are seen by Kernberg as representing the conflict between the individual's need for an object and the rage felt towards that object. They deal with the conflict by self-absorbedly becoming their own ideal self. For Kohut (1977) and Winnicott (1965) absent, insensitive, or abusive primary figures force children to retreat into themselves and become the missing ideal object. In both cases infantile omnipotence is maintained into adulthood.

A critical feature from the point of view of treatment is the high prevalence of trauma in this group. A large proportion of hospitalized borderline individuals meet diagnostic criteria for post-traumatic stress disorder (PTSD) (Gunderson & Sabo, 1993) and 70–80% have histories of severe physical or sexual abuse (Herman, Perry, & van der Kolk, 1989). The almost ubiquitous presence of trauma may help bring together conflict or deficit theories, particularly since the trauma is frequently one of relatively late childhood or even adolescence. It is conceivable that certain individuals whose early attachment relationships were insecure, and who are consequently somewhat poorer at understanding mental states in others and in themselves, when confronted with an abusing relationship respond to it by selectively obliterating detailed representations of the mental states of other attachment figures (Fonagy et al., 1995). A number of common features of borderline personality disorder could be explained in terms of the defensively deactivated mentalizing capacity of such individuals in the context of attachment relationships (e.g., confusion in interpersonal relationships, apparent callousness towards others, poor capacity to communicate).

6.05.3.2 Treatment Strategies

It is to be expected that two sets of theoretical approaches (conflict and deficit) lead to categorically different treatment recommendations. The former identifies the early interpretation of the negative transference as critical, whilst the proponents of the deficit view stress the importance of the holding environment and empathic responding. There is no shortage of forceful recommendations and warnings of the dire consequences should these not be followed (e.g., Kernberg, 1984; Ryle, 1994), but evidence supporting either position is at the moment sparse. A number of reviews have, however, brought together a generic framework for the psychodynamic treatment of borderline patients based on the assumption that both conflict and deficit models are of relevance and both would probably cause harm if inexperienced therapists were to follow the recommendations without qualification (see Gabbard, 1994; Higgitt & Fonagy, 1992; Waldinger, 1987).

6.05.3.2.1 Limits and boundaries

The therapist needs to recognize the importance of both setting definite limits for patients and the patients' likely failure to keep to traditional boundaries. The setting must be protected from the overwhelming demands which such difficult patients may produce, yet must have the flexibility to contain the patients at times when self-regulatory capacities are no longer available to them. As these remarks suggest, there are major advantages to seeing the more severe cases in institutional (although not necessarily inpatient) rather than private settings.

6.05.3.2.2 Interpretive focus

Psychological space must be created in the mind of the patient for interpretive work which assumes mentalizing (thinking about mental states in self and other). It is essential that moment-to-moment changes in affective states are noted and clarified by the therapist, even if the reason for these rapid changes of affect often remains obscure. Failures of understanding are often reacted to rather dramatically (with complete withdrawal, paranoia, physical violence, self-harming). The interpretation (more properly clarification) of these emotional reactions at their earliest stages may avoid a vicious cycle of ever-increasing anger and ever-decreasing possibility for genuine understanding. Therapists should aim to make "microinterpretations"—simple but frequent verbalizations which address states-of-mind—using words to make room for thinking and feeling without making assumptions that at times of intense affect the patient can understand complex causal relations between mental states. It should be remembered that the destruction of thought might be the strategy closest to hand for many of these patients and thus, unless cautious and nimble, the therapists may well find themselves squeezed out of the therapeutic space, where there is now no longer room for any kind of understanding.

6.05.3.2.3 Counter-transference

Feelings with borderline patients are intense. From one meeting to the next, "therapist the savior" may turn into "therapist the tormentor." At these moments several things are hard to remember. First and most obvious, that there is no truth in either attitude and that all that is certain is that nothing is permanent. Second, that there is some painful element of truth to even the wildest projection and that the therapist is a real cause as well as an imaginary one. Third, that any pretense of being unaffected by the close proximity of such intense emotion creates an atmosphere of unauthenticity, not just between therapist and patient but also within the therapist. Unfortunately, the patients' intolerance of other minds causes them to attack the space which therapists usually reserve for themselves for thinking. Mindless anxiety or a bewildered state of numbness can fill not just the session itself, but times for reflection before and after.

6.05.3.3 Handling Crises

Crises in treating borderlines are inevitable but their timing may well be a surprise. The general advice of those who regularly deal with emergencies across a wide range of contexts is that disaster planning is best when it precedes rather than follows the event. A well-rehearsed contract with a patient may go some way to limit extremes of acting out, but having a plan for dealing with suicidality, self-harm, drunkenness, intrusiveness, and sometimes violence is the key. Knowing what to do will avoid acting out on the part of the therapist which mostly takes the form of aggressive, overpunitive, rejecting actions arising mainly out of damaged self-esteem: "How can you do this to me when I have tried so hard with you?" Good collaborative relationships with colleagues also working with the patient is a *sine qua non* of psychotherapeutic treatment.

The management of crises, however, cannot be mechanistic. Careful scrutiny with the patient of thoughts and feelings that led up to the event must take place even if not at the time and not as part of the emergency procedures. The overarching goal is replacing action with mental work. Despite there being no foolproof way of preventing crises, certain patterns of therapeutic intervention (e.g., excessive passivity, complete nondirectiveness, or other expressions of rigidity and unthinking conduct) will inevitably cause these patients to incubate anxiety and "blow."

6.05.3.3.1 Desirable outcomes

The goals of long-term psychodynamic therapy are ambitious in some contexts but have to be modest with borderline patients. The process goals are largely clustered around the notion of tolerance: tolerance for affect, for fantasy, for a variety of therapeutic interventions (particularly therapist errors). The external goals are also limited. Although anxiety may abate, depression rarely responds significantly. Interpersonal issues may improve but never become normal. The behavioral aspects are most likely to respond to treatment.

6.05.3.4 Outcome Research

Evidence for the efficacy of psychodynamic therapy for borderline individuals is limited. A long-term naturalistic follow-up (Stone, 1993) of 500 patients demonstrated some degree of spontaneous remission in middle life but also high suicide rates and selective response to treatment. Clearly, the *DSM* diagnosis describes several subgroups of patients probably with somewhat different etiologies and significant differences in expected outcomes. Work at Cornell Medical Center by John Clarkin, Otto Kernberg, and colleagues may provide us with a questionnaire instrument which will assist in the assessment of suitability. Treatment drop-out rates are very high, in one sample up to 50% (Aronson, 1989). Patients who stay in treatment appear to do relatively well with success rates of 60–70% reported from open trials (Rosser, Birch, Bond, Denford, & Schachter, 1987; Stevenson & Meares, 1992; Stone, 1993).

6.05.4 FORMS OF BRIEF PSYCHODYNAMIC THERAPY

6.05.4.1 The Historical Roots of Brief Psychodynamic Therapy

Paradoxically, the prototypical long-term psychodynamic therapy, psychoanalysis, shares its roots with brief therapy. The psychoanalytic treatment of many of the pioneers of psychoanalysis would by present standards be considered brief, intensive psychotherapies. The early cathartic method advocated in Breuer and Freud (1895) may be construed as a focused hypnotic brief intervention. Freud's case load, even after his discovery of the method of free association, contained brief therapy cases including some very distinguished clients, Bruno Walter and Gustav Mahler amongst them.

Three of the early generations of psychoanalysts sharing Hungarian origins contributed most directly to brief psychodynamic interventions. These are Otto Rank, Sandor Ferenczi, and Franz Alexander. Both Rank and Ferenczi were concerned that long-term therapy could reinforce regressed overdependent aspects of the client's personality and that the goal of psychoanalytic research through the in-depth exploration of the patient's psyche may at times conflict with the immediate aim of addressing the abnormal dynamics of the patient's mental life (Ferenczi & Rank, 1925, p. 52). Ferenczi was particularly keen to discover ways in which the process of symptomatic cure could be accelerated. In the course of this research he discovered many of the central principles of behavior therapy. Because of the conservative nature of the psychoanalytic establishment, these remained outside the psychodynamic frame of reference and became a major challenge rather than part of its armamentarium. There is no difficulty in incorporating these methods into modern psychoanalysis (Fonagy, 1989; Wachtel, 1977), just as Ferenczi had little difficulty in so doing. His discoveries included the principle of exposure to combat phobic avoidance, the principle of response prevention for obsessional rituals, and the focused elaboration of key ideas akin to some strategies of cognitive therapy. Ferenczi 's aim in these and other elaborations was to accelerate the process of change. Neither he nor Otto Rank shied away from the possibility of using techniques from other therapeutic modalities (e.g., hypnosis) if these were going to advance their underlying aim of enhancing the curative emotional experience of psychodynamic therapy (Ferenczi & Rank, 1925, pp. 63–64).

Franz Alexander was influenced by Ferenczi in his training. Together with Thomas French, he elaborated Ferenczi's suggestion of provoking specific affective experiences in the therapeutic relationship. They advocated that the therapist should purposefully counteract the pathogenic influence of particular significant figures from the past. For example, the accepting attitude of the therapist may contrast with that of an excessively harsh and authoritarian parental figure. The choice of the therapist's attitude should be dictated by the history of the specific patient. Even more important than these controversial suggestions is the general framework advanced by Alexander and French which included a structured approach initiated by a detailed assessment followed by a comprehensive formulation, the setting of treatment goals, and the systematic anticipation of problems that may be encountered in the course of treatment. The total treatment package included homework assignments, a focus on current relationships, and an open acceptance of educational as well as insight-related goals of therapy.

6.05.4.2 Indications for Brief Psychodynamic Therapy

The diagnostic groups that are likely to be considered for brief psychodynamic therapy are the less severe anxiety and depressive disorders, adjustment disorders, and some of the milder personality disorders. By contrast, individuals with a history of suicidal threats, alcohol and substance abuse, poor impulse control, incapacitating depression or anxiety, or dramatic cluster personality disorders are normally deemed unsuitable (Messer & Warren, 1995). Proponents of brief therapy normally add psychodynamic criteria to the phenomenological. Sifneos (1987) for example, suggested that, in addition to a circumscribed central complaint, suitable clients would have a history of at least one good childhood relationship, a capacity to relate flexibly to the interviewer, evident psychological mindedness and a motivation for change beyond symptom relief. By contrast, Malan (1976a) lists six dynamic exclusion criteria which are the mirror image of Sifneos' selection criteria: for example, the inability to make contact, lack of motivation for treatment, rigid defenses and severe dependence. Davanloo (1980) emphasizes the importance of "trial interpretations." If clients respond to firmly put, but necessarily tentative hypotheses by a "deepening involvement," they are more likely to be regarded as suitable than individuals whose response is decompensatory (e.g., anxiety, confusion, paranoia).

Strupp and Binder (1984) also list current emotional discomfort. They suggest that patients have to be sufficiently uncomfortable with their feelings and/or behavior to seek help from psychotherapy. On the whole, brief psychotherapists recommend expressive techniques for healthier patients and supportive techniques for sicker ones (Luborsky & Mark, 1991).

No formal, structured interviews and assessments have been developed to aid clinicians in these assessments. There is, however, significant empirical data available which suggests that some of these psychodynamic parameters are pertinent to the likely success of psychotherapy. Piper and his colleagues have, however, carried out a number of excellent studies validating some of the underlying concepts. Piper, de Carufel, and Szkrumelak (1985) demonstrated that the quality of object relations (QOR) and defensive style together predicted good outcome in time-limited psychodynamic therapy. The clinical judgment of the quality of object relations is based on an evaluation of the quality of object relation patterns throughout the life span, the capacity to regulate affect and self-esteem, and historical antecedents of these (Piper et al., 1985).

Quasi-experimental studies demonstrated that clients with high QOR were more likely to benefit from therapy than low QOR ones to a clinically significant extent (Piper, Azim, McCallum, & Joyce, 1990a). QOR may be a better predictor of therapeutic alliance than measures of interpersonal functioning but may account for the latter's association with outcome (Piper et al., 1990). Norwegian studies have independently demonstrated that a clinical assessment of the patient's quality of interpersonal relations was a good predictor of long-term change following dynamic psychotherapy (Høglend, 1993a, 1993b; Høglend, Sørlie, Heyerdahl, Sørbye, & Amlo, 1993b).

6.05.4.3 Techniques of Brief Psychodynamic Therapy

6.05.4.3.1 Malan's brief intensive psychotherapy (BIP)

David Malan, a British psychoanalyst working at the Tavistock Clinic alongside one of the pioneers of object relations theory, Michael Balint, was one of the first to adapt standard psychodynamic therapy as practiced in this psychoanalytically oriented outpatient public mental health facility for brief interventions (Malan, 1963, 1976a, 1976b). The normal length of BIP is approximately 20 sessions. In the initial session(s) central conflicts for the patient are identified and the therapist focuses on these selectively, ignoring other conflicts and interpreting only those aspects of the patient's material which pertain to these concerns. There is no particular type of conflict to which Malan's approach gives preference, although Malan offers an overriding structure, similar to that of Karl Menninger, which he regards as pertinent to all conflicts. The "triangle of conflict" includes: the impulse or affect, the defense erected against it, and the symptom or anxiety which ensues after the failure of defence. An example (Malan, 1980, pp. 178–184) of a focal conflict may be someone who is angry about being imposed upon but defends against this and manifests usually intense anxiety about asserting herself and becomes depressed as a consequence. Malan recommends addressing conflict in at least three contexts: in the patient's current life, with the therapist, and in relation to past caregiving figures.

Perhaps because of its proximity to standard psychotherapeutic practice, Malan's Brief Intensive Therapy has been extensively validated empirically. Malan's own studies (Malan, 1976a, 1976b) are methodologically too weak to warrant review. However, the Canadian studies by Piper have provided evidence that (i) Malan's therapy is as effective as long-term individual or group psychotherapy (Piper, Debbane, Bienvenu, & Garant, 1984), (ii) patients undergoing this form of therapy are significantly better off in 78% of cases than untreated control patients (Piper et al. 1990), and (iii) that for highly object-related patients the accuracy of transference interpretations corresponded to outcome at six-month follow-up (Piper, Joyce, McCallum, & Azim, 1993). Norwegian studies demonstrated that level of insight gained (as assessed independently) in 43 outpatients correlated with overall dynamic change at four-year follow-up (Høglend, Engelstad, Sørbye, Heyerdahl, & Amlo, 1994).

There are controversial findings concerning the role of transference interpretations. Malan reported that the frequency of therapist, parent, current figures triangular interpretations correlated with therapeutic outcome (Malan, 1963, 1976b). This finding corresponds to Strachey 's classical assumptions concerning "mutative" aspects of interpretation (Strachey, 1934). Unfortunately, although preliminary replications confirmed Malan's observations (Marziali, 1984; Silberschatz, Fretter, & Curtis, 1986), more careful analyses by the Canadian group indicated that, for low QOR patients at least, the frequency of transference interpretation was associated with less rather than more symptom change (Høglend et al., 1993a; Piper, Azim, Joyce, & McCallum, 1991).

An interesting study by another Norwegian research group has demonstrated the effectiveness of Malan's BIP in reducing the relapse rate following clomipramine treatment of panic disorder (Wiborg & Dahl, 1996). Thus Malan's therapy is relatively well validated although the clinical groups on which the treatment was assessed are relatively heterogeneous. Studies also offer some indication that the treatment process corresponds to those hypothesized by the originator of the therapy, although evidence on this point remains equivocal.

6.05.4.3.2 Sifneos' short-term anxiety-provoking psychotherapy (STAPT)

In the USA, short-term psychodynamic psychotherapy retained close links with the classical ego psychology tradition. Sifneos developed a psychodynamic treatment focused on the oedipal concern of individuals whose psychological problems could be relatively readily linked to this common type of unconscious conflict (Sifneos, 1979, 1987, 1992). Sifneos, probably accurately, pointed out that psychodynamic therapists were frequently more ready to acknowledge issues of dependency and frustration in relation to caregiving figures than concerns about childhood sexual fantasies about parents of the opposite gender. The recommended strategy is for the therapist to listen carefully for material pertaining to oedipal issues and to address this directly without regard to the defenses which individuals may have erected to protect themselves from the anxieties these thoughts might engender.

Sifneos adopts a somewhat didactic stance and does not shrink from explaining his reasoning in identifying material as relating to oedipal anxieties. He also confronts patients' defenses, being particularly sensitive to instances of intellectualization. A strong point of his approach is the availability of a relatively comprehensive manual for short-term anxiety-provoking psychotherapy (Sifneos, 1992).

There is only very limited evidence available to support the usefulness of this approach. Sifneos and colleagues reported a comparison of 22 treated patients and eight waiting list controls (Sifneos, Apfel, Bassuk, Fishman, & Gill, 1980). While 18 out of 22 were reported to have recovered in the treated group or to be much better, none of the waiting list group reported a similar degree of change. In a somewhat larger study reported in 1987, 30 of 36 patients were rated as having recovered or being much improved whereas 80% of the 14 waiting list patients were unchanged. Unfortunately in neither study were the measures sufficiently clearly described to permit generalization, nor were raters blind as to treatment group. Independent studies examining the relationship of therapeutic process to outcome found no evidence that therapists' competence at practicing STAPT predicted good outcome. In fact, competence was inversely related to improvement (Svartberg & Stiles, 1992, 1994).

6.05.4.3.3 Davanloo's intensive short-term dynamic psychotherapy (ISTDP)

Davanloo's approach is also quite confrontational, aiming to create a degree of emotional arousal and even discomfort while trying to address presumed feelings in clients which they might have consistently avoided (Davanloo, 1978, 1980). Davanloo's aim is to intensify the emotional charge of the therapeutic situation so that within it important past emotionally charged experiences will once again come to life. The therapeutic strategy entails offering empathic support in relation to the past hardships suffered by the patient. Nevertheless, the pattern of interaction as revealed by Davanloo's detailed account is one of tenacious and unremitting confrontation of the patient, focused on the patient's problems and defenses against them, identified on an initial inquiry.

There is a single trial which supports the effectiveness of this form of therapy (Winston et al., 1991). Thirty-two patients were assigned to one of two brief psychodynamic therapies. Patients assigned to the other therapy (brief adaptive psychotherapy) did comparably to those receiving ISTDP and both did substantially better than the waiting list controls. In a follow-up and extension of this investigation (Winston et al., 1991, 1994) a larger sample of patients were seen to maintain their improvement. An interesting feature of this investigation was the inclusion of some nondramatic Axis II patients. The study, however, only used self-report measures and did not succeed in differentiating the two forms of psychotherapy.

6.05.4.3.4 Luborsky's supportive-expressive time-limited therapy (SETLT)

Luborsky's brief psychodynamic approach is fundamentally an adaptation of psychodynamic therapy defined quite broadly (Luborsky, 1984). The technical principles are outlined by Luborsky and Mark (1991). They include recommendations for the therapist to be sensitive to allow the patient to form a "helping alliance," to identify and respond about central relationship patterns, and identify where the client's symptoms fit into these. They explicitly recognize the patient's needs to test the relationship in transference terms and recommend that the patient's symptoms should be identified as problem-solving coping patterns.

Thus, Luborsky's approach has two critical focuses. The first is the relationship patterns which they label as "core conflictual relationship themes" (CCRTs) (Luborsky & Crits-Christoph, 1990). These themes consist of three components: the wish (or need), the anticipated response from others to this wish, and the response from the self to the other's response. These themes are conflictual because the response of the other to the wish is anticipated to be negative. The CCRT is derived from clinical material. "Relationship episodes" are identified from transcripts of sessions where the patient narrates an episode of interaction. The CCRT represents a summary of the most frequent types of components. Luborsky and Schaffler (1990) offer an illustration of an individual whose wish is to be assertive, dominant yet reassured, but anticipates disapproval and is left feeling annoyed, angry, and upset about not feeling in control. It is important to note that relationship episodes may be drawn from narratives which apparently do not involve the self, and in this respect the method is analogous to psychodynamic psychotherapists' approach to the understanding of the transference.

Considerable research supports the value of CCRTs (see Luborsky & Luborsky, 1995). The reliability of both the overall formulation and its components is relatively high when performed by trained judges (Crits-Christoph, Luborsky, Popp, Mellon, & Mark, 1990). The measure is also replicable across settings. The CCRT with the therapist parallels the CCRT for others in the patient's life (Fried, Crits-Christoph, & Luborsky, 1990) and even the CCRT derived from patients' dreams (Popp, Luborsky, & Crits-Christoph, 1990). The extent of these observed congruencies indicates that these patterns of representations of relationships are stable structures of the personality. It is an important validation of Luborsky's approach that the frequency of conflict themes negatively correlated with measures of change (Crits-Christoph & Luborsky, 1990).

The second component of Luborsky's approach is the helping alliance. In addition to attending to current, past, and transference relationship fears, therapists are required, through their timing and restraint in responding interpretively to clients' material, to convey respect, acceptance, realistic optimism, to encourage self-expression and thus create a collaborative atmosphere (Luborsky, 1984, pp. 81–89). The helping alliance thus generated has two dimensions according to Luborsky: the patient perceives the therapist as a provider of help that is needed, and the patient perceives the therapy as a collaborative exercise (Luborsky, Crits-Christoph, Mintz, & Auerbach, 1988).

Helping alliance has been shown to be positively associated with outcome. The duality of Luborsky's approach (CCRT and helping alliance) is supported by critical findings that the quality of the helping alliance and therapist accuracy (as defined in terms of the degree of correspondence with the CCRT) independently predict outcome (Crits-Christoph, Barber, & Kurcias, 1993; Crits-Christoph, Cooper, & Luborsky, 1988). In the more recent study, there was an indication that accuracy of early intervention had a positive impact later on in therapy. Thus it is possible that whilst the quality of the helping alliance may be the immediate cause of change, this aspect of the relationship may be enhanced by accurate formulations by the therapist.

Although no randomized controlled trials compare Luborsky's supportive-expressive therapy with no treatment controls for milder neurotic disorders, the Penn project yielded numerous important findings concerning the outcome of this treatment. Most impressively, three-quarters of the large group of patients treated showed moderate or much improvement with an average effect size of over one standard deviation, and much of this gain was maintained at one-year follow-up (Luborsky et al., 1988). In addition, in a major study comparing supportive-expressive therapy, cognitive therapy, and drug counseling for opiate-dependent patients, Woody and his colleagues (Woody, Luborsky, McLellan, & O'Brien, 1990; Woody et al., 1983; Woody, McLellan, Luborsky, & O'Brien, 1987) found supportive-expressive therapy to be effective in reducing psychiatric symptoms, opiate-positive urine specimens, employment, and legal problems. In a replication study the same group demonstrated that supportive-expressive therapy was a useful adjunct to drug counseling as part of a typical community-based drug program (Woody, McLellan, Luborsky, & O'Brien, 1995). It is notable that supportive-expressive therapy was particularly helpful in maintaining improvement at follow-up. Although studies on depressed or anxious individuals would be helpful, it is clear that supportive-expressive therapy is a valuable intervention strategy.

6.05.4.3.5 Strupp's time-limited dynamic therapy (TLDP)

The hallmark of Strupp's model of therapy lies in its interpersonal emphasis and the persistent use of the transference relationship in the here and now. The therapy has its intellectual roots in Sullivan's (1953) interpersonal psychoanalytic tradition. Binder and Strupp (1991) understand psychopathology as arising out of cycling maladaptive patterns whereby patients perceive themselves in maladaptive roles with self-defeating expectations, negative self-appraisals and adverse affects consequent on these. The cyclical nature of the process arises out of the client's unconscious tendency to induce others to behave in ways that reinforce the patient's negative and painful expectations, thus further reinforcing these expectations and the interpersonal behaviors which arise from these. This formulation is close to that proposed by Joseph Sandler in the 1970s and early 1980s (Sandler, 1976b, 1990, 1992).

Similarly to Luborsky, Binder and Strupp (1991) distinguish actions of the self, expectations about others' actions, acts of others towards the self, and acts of the self towards the self. Although these terms sound somewhat behavioral, from their description it is clear that the authors are concerned with mental representation of these interpersonal behaviors rather than the behaviors themselves. The cyclical maladaptive patterns are identified by the therapist on the basis of the client's characteristic patterns of relating which involve the patient's perception of self, others, and their interactions. In therapy, maladaptive patterns are identified, their meaning interpreted and the client is helped to articulate and modify entrenched and limiting views of the self, others, and their interaction.

TLDP creates individualized theories for each client, making use of these four headings. The theories connect together behavioral and experiential phenomena which otherwise would appear discontinuous (Strupp & Binder, 1984). The patient's relationship with the therapist is seen as a key component of the change process. This new relationship may disconfirm maladaptive expectations of others and provides a chance to examine the way that patients' acts towards the self may ensnare them in maladaptive patterns (Binder & Strupp, 1991, p. 142). The Vanderbilt University Project, of which Strupp's TLDP is a product, was key in identifying the therapeutic relationship and the nature of the patient's experience with this new figure as a key aspect of therapeutic change. An important finding of the project was that successful treatments could be predicted on the basis of the patient feeling accepted, understood, and liked by the therapist as early as the third session of treatment (Hartley & Strupp, 1983; O'Malley, Suh, & Strupp, 1983; Windholz & Silberschatz, 1988). The importance of the relationship is further underscored by the absence of an observed significant difference between trained psychotherapists and sensitive but untrained college professors in their ability to administer time-limited dynamic therapy (Strupp & Hadley, 1979).

6.05.4.3.6 Weiss and Sampson's plan formulation method

Weiss and Sampson (1986) proposed a further useful framework for the articulation of clinical focus. At the core of the theory is the assumption that patients enter therapy with an unconscious plan about how they may overcome their problems with therapeutic help. Pathogenic beliefs are "obstacles" to this. Weiss and Sampson assume that patients will inevitably "test," in the context of their therapy, whether their pathogenic beliefs are true. If the therapist "passes" the test, the patient's experience will contribute to the enlargement of understanding ("insight") to counteract the pathogenic belief. An example of a pathogenic belief may be an individual with a mother unhappily married throughout the patient's childhood, unconsciously believing that her happiness means that her mother will feel hurt and abandoned. The patient might then test the therapist to see if the therapist also expects the patient to be self-sacrificing and feigns hurt if the patient attends "selfishly" to her own needs. Such an unconscious belief arises out of actual historical experience, rather than an unconscious wish to harm the mother (Sampson, 1992, p. 515).

It follows that the principal therapeutic task of short-term dynamic psychotherapy is that the therapist should recognize the patients' conscious or unconscious attempts to replicate with the therapist their pathogenic situations or past life experiences. Therapists may be deemed to pass the patient's test by giving recognition of the situation through appropriate interpretation or nonverbal behavior, such as maintaining their therapeutic stance despite the patient's determination to traumatize and unsettle them.

Thus the nonoccurrence of certain strongly anticipated outcomes may in and of itself be therapeutic.

Research, building on this approach, has demonstrated that plan formulation may be reliably assessed using recorded clinical material (Curtis, Silberschatz, Sampson, & Weiss, 1994; Curtis, Silberschatz, Sampson, Weiss, & Rosenberg, 1988; Silberschatz & Curtis, 1993) and that such plans are stable over time (Collins & Messer, 1991). The compatibility of the therapist's interventions with independently assessed plans of the patient was found to predict progress in the early and middle phase of therapy (Messer, Tishby, & Spillman, 1992). One of the strengths of Weiss and Sampson's approach is that it may be assumed to apply to patient's behavior, regardless of the orientation of the therapist. Indeed, the Plan Compatibility of Interventions Scale predicts response to therapist intervention in cognitive-dynamic, as well as object-relations theory-based approaches (Tishby & Messer, 1995). It should be noted that in these studies outcome refers to relative improvements within the therapeutic process rather than overall improvements at the end of therapy. In fact, no large-scale study of Weiss and Sampson's method has as yet been undertaken.

6.05.4.3.7 Horowitz's person schema theory

Horowitz (1988a, 1988b, 1991a) has offered a general systems theory reformulation of object relations constructs strongly influenced by Bowlby's (1973, 1980) notion of internal working models, Sandler's (1976a, 1976b) notion of role responsiveness, and Kernberg's (1975, 1984) model of self–object dyadic units, as well as current cognitive science. He proposes that through development the individual evolves multiple schemas of self and other which exist either as person schemas or as role-relationship models (RRMs). He defined the former as nonexperiential (codifications and) meaning structures with the potential to influence the formation of the self-concept. They are seen as combining in more complex schemata of the self-in-relationship-with-the-other (see also Stern, 1994). The self-schemas integrate the individual's prior experiences and, ideally, present a stable image of the self as invulnerable. These RRMs are templates of relationships which can affect the formation of the concept of relationships as well as actual patterns of interpersonal transactions. RRMs are assumed to specify interaction patterns as sequences, much like scripts of plays, but in terms of expectations, wishes, and appraisals of one person toward the other.

RRMs are organized into affectively coherent configurations (RRMCs) each of which are made up of RRMs with a set of wishes, fears, and defenses in relation to a specific theme. Desired RRMCs contain strong wishes, and dreaded RRMCs are made up of feared RRMs. The derivatives of defensive operations are compromise RRMs which can be either adaptive (if successful) or problematic (if not), but in either case the affective valence of the RRM has been attenuated. A problematic RRMC will contain either negative affects or maladaptive traits, at a more manageable level than in dreaded RRMs. If the enactment of a desired RRM is blocked by the threat of entry of a dreaded RRM, an attenuated solution to the desired RRM is found which provides a partial gratification of the wish. An RRMC may represent a firm linkage between RRMs so that a mental state organized by a desired RRM can trigger a mental state organized by a dreaded RRM. Such mental states may be represented by patterns of activation, such as those envisaged in parallel distributed computer models of neural activity.

Horowitz (Horowitz, 1991a; Horowitz, Fridhandler, & Stinson, 1991) views anxiety as a mismatch between schemas and incoming information. If information is interpreted as suggesting a dreaded schema, anxiety will result. If a wished-for RRM is to be in relation with a powerful guiding figure but this brings with it a dreaded RRM of a state of exploitation, the individual will experience anxiety at the moment of being approached by an actually benign but powerful figure because this person's presence brings with it the threat of exploitation. This may put control processes in place which will reduce the distance of this figure. The anticipation of the dreaded RRM is experienced as anxiety without the dreaded RRM ever being fully activated (i.e., coming into awareness). The control processes can, in the extreme, become severe enough to imply personality disorder, in this case perhaps a somewhat schizoid state.

In certain cases the dreaded RRM may be partly experienced and this is also expected to lead to anxiety. A woman who lost her husband, whom she felt was dependable but whom she did not love, may develop anxiety when she starts a relationship with another man for whom she has more intense feelings. The dreaded RRM which is briefly activated is the experience of seeing herself as the unfaithful wife humiliating her dependable but unexciting husband (see Horowitz, 1991a).

In post-traumatic stress disorder an experience is vividly encoded in memory. Because it is not integrated into the individual's prior integrated self-schema, it is liable to be activated as incoming information, and misinterpreted to imply the reoccurrence of the trauma. The trauma may also threaten to actualize a dreaded RRM, for example, of the self as weak and overwhelmed. The compromise state may be denial, depersonalization, restricted affect, and hypervigilance (see Horowitz, 1986, 1988a). In generalized anxiety disorder the dreaded RRM is seen as inescapable, either because a compromise cannot be reached or because the desired RRM contains some dreaded components (e.g., RRM of the self as blundering and stupid in face of punishing mentors in a situation which is experienced as one of constant evaluation).

Horowitz's model is most extensively elaborated for the 12-session treatment of post-traumatic stress disorder (Horowitz, 1986, 1991b). The therapy is aimed at the realignment of RRMs. In the "intrusive repetitive phase of the stress response" the recommended strategy is largely supportive and ameliorative. The therapist takes on the auxiliary ego function of self-regulation and the reduction of overwhelming affect states. In the "denial numbing phase" of the stress response, Horowitz emphasizes the reduction of controls over self-expression and emotional exploration. The stress event remains the therapeutic focus, serving to organize the therapist's activities in relation to the transference and other feared topics. Time limit and termination are also explicitly identified as themes to be addressed from as early as session six.

Horowitz's model stands out among psychodynamic formulations for brief therapy in offering a comprehensive framework specific for a range of psychiatric disorders at the same time as remaining amenable to empirical examination. Clinical judges appear to be able reliably to assess roles, characteristics, and traits of self and others, link them in wish-fear dilemmas, and assemble them into presumed RRMCs of particular patients observed in psychotherapy sessions (Horowitz, Milbrath, Reidbord, & Stinson, 1993; Horowitz, 1995; Horowitz & Eells, 1993). There appears to be considerable convergence between RRMC formulations and Luborsky's core conflictual relationship theme approach (Horowitz, Luborsky, & Popp, 1991). Unfortunately, randomly controlled outcome studies on Horowitz's therapeutic strategies are lacking.

6.05.4.3.8 *Mann's time-limited psychodynamic therapy (TLPT)*

Of the brief psychodynamic therapies it is perhaps Mann's approach that takes the time-limited nature of the intervention most seriously. He believes that the time limitations inevitably brings into the foreground the difficulty most of us experience with separation (Mann, 1973). Time-limited psychotherapy is focused on the patient overcoming separation–individuation issues through the mastery of separation anxiety. The conflicts encountered in this context concern independence, activity, self-esteem, and delayed grief. Mann suggests that the beginning of therapy recreates a symbiotic unity, the middle phase recreates ambivalence, whilst the end phase introduces the necessity to give up the object, but this time without hatred, anger, despair, or guilt.

Mann's formulation focuses on clients' feelings about themselves in relation to the painful events described. He acknowledges the patients' active coping efforts and their experience of failure with regard to being able to adapt adequately to this distress. Patients' symptoms are not directly addressed but rather the underlying emotional state, particularly their injured self-esteem, is highlighted. In contrast to Sifneos and Davanloo, Mann is not at all confrontative and uses confirming and mirroring to bypass defenses rather than tackling them head on (Mann & Goldman, 1982). The therapy lasts 12 sessions excluding sessions for history taking. The initial phase of four sessions sets up an alliance generating hope and frequently a remission of symptoms. In the middle phase ambivalence sets in as patients come to recognize that their unconscious expectations will not be fulfilled. In this phase the therapist is no longer simply mirroring and affirming but is introducing clarifications, mild confrontations, and interpretations especially regarding the current situation of the person's life and thus directly reinforcing the patient's separateness. In the final four sessions the patient's reactions to termination are the focus. The therapist attempts to build a sense of mastery and competence at the same time as addressing the patient's disappointment and ambivalence concerning separation, often linked to past experiences of inadequate resolutions of separation and loss.

In this therapy the time-limited nature of the intervention is used directly to elicit a set of conflicts associated with earlier separations and losses where maladaptive emotions were generated (anger, disappointment, sadness, guilt) which ultimately resulted in the disorder which led to the referral. The therapy creates a situation where separation can occur with a degree of resolution which is less contaminated by negative emotions. The internalizations thus lead to a less angry, more benign introject.

Although Mann's therapy is well-established, it has not yet generated a great deal of research.

A notable exception is a study reported by Shefler and colleagues (Shefler, Dasberg, & Ben-Shakhar, 1995). This was a randomized controlled trial with a waiting list control design. Only nine out of the 33 patients did not have a *DSM* diagnosis. The effect size was only fractionally below one on a range of measures. However, the patients accepted for the trial were highly selected and only 11% of those seen were included in the trial. In an uncontrolled trial, Joyce and Piper (1990) found that 14 patients diagnosed with separation-individuation problems were highly successfully treated in 12 sessions using Mann's technique and the results were maintained at six-months follow-up. There is further evidence that TLPT reduces drop-out rate (Sledge, Moras, Hartley, & Levine, 1990), and patients who do well show a trend towards increasingly appreciating their sessions as the treatment progresses (Joyce & Piper, 1990).

Mann's approach has been criticized for attempting to provide a generic model on the basis of a specific model of pathogenesis (Grand, Rechetnick, Podrug, & Schwager, 1985; Westen, 1986). Some fundamentally disagree that termination is an inevitable crisis in therapy (Quintana, 1993). It is also unlikely that Mann's model of cure is accurate. A process such as internalization is more likely in long-term than in short-term therapy (Westen, 1986). However, although the treatment is only appropriate for a relatively limited group of patients, its very specificity may be its strongest feature. If a method was found to identify this group using reliable operational criteria which also matched concerns of purchasers of mental health care (e.g., generalized anxiety disorder), this form of therapy could be a valuable component of the repertoire of psychodynamic approaches.

6.05.4.3.9 Ryle's cognitive analytic therapy (CAT)

Relatively unknown in the USA, but increasingly influential in the UK, is CAT, a time-limited integrative psychotherapy (Ryle, 1982, 1990). The procedural sequence model (PSM) is the framework used by Ryle to restate psychoanalytic ideas using cognitive language. The model conceptualizes intentional acts as procedures entailing a series of steps including appraisal of plans and predicted consequences, the evaluation of the consequences of the enactment, and the confirmation or revision of aims and means following this evaluation. The therapeutic method is centered on the process of reformulation. Over the course of the first month of the treatment, patients normally engage in monitoring their symptoms, undesirable behaviors, and mood shifts. Neurotic patterns are described in terms of three categories: dilemmas, traps, and snags. Dilemmas, traps, and snags are described in the "psychotherapy file" which is given to patients at the end of the first session. They rate items within it to indicate how characteristic they are of them. These ratings are discussed at subsequent sessions when main target problems (TPs) are also established, on the basis of the self-monitoring, together with the underlying dilemmas, traps, and snags. Traps are things we cannot escape from, such as "a fear of hurting others" trap, "trying to please" trap, or "social isolation" trap. Dilemmas are false choices about oneself or about one's relation to others, for example, "either I feel I spoil myself and am greedy or I deny myself things and punish myself and feel miserable" or "either I am a brute or a martyr." Snags are ways we stop ourselves from changing, for example, "for fear of the response of others." The dilemmas, traps, and snags characteristic of an individual are the target problem procedures (TPPs) which are thought to underlie that person's central problems. "TPs" and "TPPs" form the agenda of the therapy. The remaining sessions (usually once a week over three months) are devoted to recognition of the TPPs using diaries and other self-monitoring devices as well as close monitoring of the client's behavior in the therapeutic situation. Modification of TPPs is principally achieved through behavioral techniques such as role play, as well as enhanced self-reflection. The explicit noncollusive relationship with the therapist is also thought to facilitate the development of new procedures.

Ryle (1985) incorporated object-relations theory into CAT introducing the notion of reciprocal role procedures. These are thought to develop on the basis of early object relationships. It is assumed that a relationship teaches children both the behaviors expected of them and the behaviors they expect of others. Self-management is learned through incorporating into the child's behavioral repertoire the caretaker's behaviors.

The emphasis in CAT is on early and profound deprivation as the cause of primitive defenses such as splitting, which characterizes individuals who fail to integrate their self-structure and elicit confirmations from others for each of their split-off self states. Whereas neurotic clients restrict or distort their procedures, borderline personality disorder patients manifest dissociated self-states containing different procedures in each.

Therapists summarize their assessments and present it to the client in writing after the fourth session. These summaries represent client history and present circumstances and trace how current problematic procedures could be repetitions of early harmful patterns or are solutions to early situations. The accounts conclude with a list of problem procedures identified and attempt to anticipate how these may influence the course of therapy. A further tool used in CAT is the sequential diagramatic reformulation (SDR) which is a flow diagram representation of how TPPs maintain neurotic patterns.

Thus CAT is a genuine integration of cognitive therapy (Beck, 1976) and object-relations theory-oriented psychodynamic therapy (Ogden, 1986). The approach to psychodynamic diagnosis is similar to many considered above, particularly Luborsky and Horowitz. The therapeutic techniques suggested are innovative and share much with schema-oriented cognitive therapy where emotional problems are seen as the reactivation of schemas which have been dormant for many years (Beck & Freeman, 1990; Bricker & Young, 1993; Young, 1990). Ryle's integration also has much in common with other integrative models such as Gold and Wachtel's "cyclical psychodynamics," which also emphasizes self-maintaining vicious cycles and intra- and inter-psychological processes and structured intervention techniques (Gold & Wachtel, 1993). Safran (1990a, 1990b) also links concepts of interpersonal schema and the cognitive interpersonal cycle, and the therapy program outlined has as its target the disconfirmation of dysfunctional interpersonal schemas. CAT, however, is far more coherently integrated with the traditional psychodynamic formulations than any of these alternatives (e.g., 1992; Leiman, 1994b; Ryle, 1994).

The procedural sequence object relations model (PSORM) illustrates the thoughtfulness of this integration. The PSORM identifies procedural patterns which explain the persistence of neurotic behavior. For example, self-destructive acts may be attributed to a dilemma ("as if I must harm myself or harm others") or to a snag ("as if guilty and therefore self-punishing"). Within SDR the self-maintaining nature could be clearly demonstrated through the connection between procedures. For example, the expectation of abandonment may generate a dilemma between being involved and thus risking abandonment and avoiding closeness. Being involved thus necessitates procedures for controlling emotionally significant others by compensatory procedures such as bulimia, that are seen as a substitute for emotional emptiness. The PSORM postulates reciprocal role patterns which constitute a central core and are stated in terms of inner parent–inner child (IP–IC) relations. An example may be a powerfully rejecting inner parent relating to a submissive and needy inner child. The reciprocal nature of the role patterns encompass psychodynamic concepts such as identification, introjection, and projection, internal objects and part-objects. Roles which are experienced as untenable are projected, that is induced in the other, and can be replaced by symptomatic procedures or defensive ones. Procedures acquire their stability from confirming reciprocations which are generally readily elicited from others, thus leaving the central core repertoire unchanged. While Ryle and others writing from a CAT perspective are keen to acknowledge Soviet theoreticians such as Vygotsky, Bakhtin, and Leonjew (e.g., Leiman, 1994a), their views are consistent with psychoanalysts writing in the interpersonalists' tradition (e.g., Mitchell, 1988).

The key difference between CAT and traditional psychodynamic therapy is the shift from interpretive work to description. The CAT therapist describes the state of affairs, often in writing, which is then subject to discussion and modification in direct therapeutic conversations. Ryle repudiates interpretive techniques as potentially regression-inducing, reflecting an unbalanced power relationship between client and therapist and feeding on the omnipotent fantasies of the therapist (Ryle, 1992, 1993). Ryle's approach lends more weight to conscious processes and his technique is based on insight coupled with the activation of self-corrective mechanisms. It is striking that, notwithstanding the emphasis on such mature mental processes, Ryle and his colleagues have reported significant successes in the brief psychotherapeutic treatment of borderline personality disorder. In an ongoing study, BPD patients are offered up to 24 sessions of CAT and follow-up sessions at one, two, three and six months. There is a three-month and one-year follow-up. Initial results are promising (Ryle, 1995). Eight out of 13 patients no longer meet BPD criteria four months after termination but seven were rereferred for a variety of other treatments. Five patients assessed at one year all showed continuing reductions in symptomatology and only one has remained in treatment.

A number of other outcome studies support the usefulness of CAT. A study of 48 outpatients randomly assigned to 12 sessions of CAT or Mann-type brief therapy demonstrated the superiority of CAT on a grid measure of change of construing problems (Brockman, Poynton, Ryle, & Watson, 1987). Unfortunately the measure was neither standardized nor sufficiently independent from the treatment to justify firm conclusions. A study of poorly controlled diabetics randomized 32 patients to intensive education or CAT (Fosbury, 1994). At nine-months follow-up CAT-treated patients had better diabetic control in terms of $HbAl^c$ levels. Other studies were either uncontrolled clinical reports (e.g., Cowmeadow, 1994; Duignan & Mitzman, 1994; Pollock & Kear-Colwell, 1994) or yielded insignificant differences between CAT and control treatments (e.g., the outpatient treatment of anorexia; Ryle, 1995). Thus the empirical basis of CAT cannot yet be considered well-established (although relative to many other psychodynamic treatments its empirical status is highly favorable).

6.05.4.3.10 Hobson's conversational model

An approach which integrates many of the characteristics of the brief psychodynamic approaches considered above is the conversational model outlined by Hobson and his colleagues (Goldberg et al., 1984; Hobson, 1985). The approach combines psychodynamic, interpersonal, and experiential concepts, and emphasizes the therapist–client relationship as the main vehicle for revealing and resolving interpersonal difficulties. In contrast to a number of other short-term therapies, therapists are encouraged to present their views as tentative statements rather than assertions and to make clear that these are open to correction and modification. The therapy is conceived of as an interpersonal negotiation, with therapists inviting elaboration of their ideas by the patient, as well as feedback. The language of the treatment is one of mutuality, with the therapist putting forward hypotheses concerning the client's experiences and possible relationships between these. The therapy has been manualized as part of the Sheffield Psychotherapy Project under the direction of David Shapiro (Shapiro & Firth, 1985).

A unique outcome study by Shapiro and colleagues (Shapiro et al., 1994) assessed the effectiveness of this mode of intervention, contrasting it with cognitive-behavioral therapy in a sample of 117 patients. Both therapies were administered for either eight or 16 weeks. Overall, both therapies were found to be effective and to have comparable results. There was an interaction between initial symptom level and duration of therapy. Patients with severe depression showed significantly better outcomes when they received 16 weeks of therapy. Eighty-eight percent of the sample were followed up one year after the end of treatment (Shapiro et al., 1995). Of the 103 patients, 52% were defined as treatment responders (remained asymptomatic for four months). Of these, 57% maintained their gains, 32% partially maintained their gains, and 11% relapsed. No differences were found between cognitive-behavioral and psychodynamic therapy, although patients who only received eight sessions of psychodynamic therapy did less well than those who received eight or 16 sessions of CBT.

While this particular form of therapy is neither widely known nor widely practiced, it is unique in terms of having been subjected to a rigorous randomized, controlled trial. As the methods used in Hobson's conversational model are fairly generic and consistent with most psychodynamic approaches, the Sheffield psychotherapy trial provides encouraging evidence for the value of brief psychodynamic approaches for the treatment of one of the most common disorders, major depression.

6.05.5 CONCLUSIONS

This chapter has reviewed psychodynamic approaches to adult mental health problems. Psychodynamic therapy is most appropriate for individuals with psychiatric disorder who are relatively well-functioning and have a capacity to understand and respond to interpretive work. The chapter reviewed key clinical concepts in psychodynamic work and demonstrated an increasing concern among psychodynamic clinicians with feelings and ideas provoked by the therapeutic situation itself. Long-term psychodynamic therapy was illustrated in the review of therapeutic strategies with individuals with a borderline personality disorder diagnosis. Several forms of brief psychodynamic therapy were discussed, together with evidence for their effectiveness.

No single approach to such brief treatments emerged as clearly superior to others. While there is a surprising amount of empirical work which has been performed over recent years, few of the studies appear to be conclusive. But, taken together, they underscore the merits of the psychodynamic approach. There is good evidence that psychodynamic therapy is effective with depressed, substance abusing, and some mixed groups of neurotic patients. There are indications of its appropriateness for individuals with PTSD, physical illnesses such as diabetes, and even BPD. Clearly much empirical work remains to be done to identify which of these treatments has the greatest potential value for which patient group.

Work over the last few decades, however, goes a considerable way towards overcoming many of the weaknesses frequently noted in connection with this approach. A number of psychodynamic clinicians have done extensive work on operationalizing their interventions, specifying modifications to generic approaches to make them more appropriate with particular clinical groups, to provide information concerning the way theories of pathology may relate to aspects of technique, to focus and shorten interventions in order to enhance their cost-effectiveness, to provide empirical evidence concerning suitability, and develop specific measures of therapeutic outcome to relate the goals of interventions to the outcomes observed.

Psychodynamic approaches have been around for over 100 years. Considering the mature nature of this category of clinical interventions, the amount of empirical work available in the literature is lamentably small. The underlying trend is for an improvement in this state of affairs. The integration of cognitive and psychodynamic approaches has certainly facilitated this process. Changes to the systems of health care delivery certainly represent a threat to psychodynamic approaches. However, the priority for psychodynamic researchers must be clearly to establish which clinical context is uniquely suited to this approach. There is no doubt that, in the past, psychodynamic clinicians have made exaggerated claims concerning the value of this mode of therapy.

The first decade of the twenty-first century should be a period of readjustment where empirical work could establish the true value of psychodynamic therapy in specific clinical contexts. Purchasers and users of these services have been undoubtedly patient in waiting for such data. Their faith in this approach has probably been fueled by the exceptional intellectual contributions made by many of those who have occupied leadership positions in the psychodynamic field as well as the value of psychodynamic theoretical contributions. Equally there is no doubt that their patience is wearing thin and that compelling empirical data of efficacy is urgently required if this form of therapy is to retain a legitimate place in handbooks such as the present one.

6.06.1 INTRODUCTION

It is only since the late 1940s that drug treatment has been able to play a useful role in the management of psychiatric disorders. Little is known about the pathophysiology of psychiatric illness, and the drugs that are currently in use were discovered by chance or by modification of compounds known to be efficacious. Indeed, such neurochemical theories as there are of psychiatric disorder have, in the main, been derived from a knowledge of the pharmacological effects of psychotropic drugs in animal experimental studies.

Drug treatment now plays in indisputable role in management of severe psychiatric disorder, such as schizophrenia and bipolar disorder. Drugs are also commonly used to treat less severe illnesses, such as depressive and anxiety disorders. Wherever drug treatments are used, they should form part of an overall management plan that takes into account psychological and social needs of the individual patient and their family.

6.06.1.1 History of Drug Treatment in Psychiatry

Drugs that produce changes in the function of the central nervous system, such as opiates and anticholinergic agents, have been used in the treatment of mental disorders for hundreds of years. Although some of these drugs may have had calming effects, they were of no specific value in the treatment of psychiatric disorders. Particular drug treatments tended to be used because their cause was espoused by vigorous and eminent physicians rather than on the basis of proven efficacy. In any case, assessment of efficacy depended on uncontrolled clinical observation.

The first drug that was discovered to have a specific effect on a prticular psychiatric disorder was lithium (Cade, 1949; Table 1). Lithium is a toxic agent and Cade's important clinical observations did not make a significant impact on clinical practice until the following decades when controlled trials showed that lithium was effective in both the acute treatment of mania and the prophylaxis of recurrent mood disorders. In addition, monitoring of plasma lithium levels enabled safe dosing regimes to be established.

Since the late 1960s there has been a period of consolidation in psychopharmacology during which clinical trials have been extensively employed to refine the indications of particular drug treatments and to maximize their benefit risk ratios. New compounds have continuously become available but because, in the main, these agents have been derived from previously described agents, their range of activity is not strikingly different from their predecessors. In general, however, the newer agents are better tolerated and are sometimes safer, and both these developments are important for clinical practice.

It is, perhaps, possible now to be more optimistic about the prospects for advances in psychopharmacology. There is, for example, rapidly increasing knowledge about the nature of chemical signaling in the brain. A multiplicity of neurotransmitters and neuromodulators interact with specific families of receptors, many of which exist in several different subtypes. Several of these receptors have been cloned and selective agents for them are becoming available. We are also learning much more about how these chemical messengers may modify behavior through their interactions with specific brain regions and distributed neuronal circuits.

Table 1 Introduction of some drug treatments in psychiatry.

Year	*Drug treatment*
1949	Lithium
1952	Chlorpromazine
1954	Benzodiazepines
1957	Iproniazid (MAOI)
1957	Imipramine
1971	Carbamazepine
1980	Selective serotonin reuptake inhibitors
1988	Clozapine for treatment-resistant schizophrenia

The availability of novel compounds, likely to have a quite different range of behavioral effects compared to currently available drugs, will lead to some exciting developments in psychopharmacology. It seems probable, given the complexity and multifactorial origin of psychiatric disorders, that detailed knowledge of etiology and pathophysiology, may lag behind advances in therapeutics. This, of course, is not uncommon in general medicine but serves to reinforce the importance of controlled clinical trials in the assessment of new psychopharmacological treatments.

6.06.1.2 Mode of Action of Psychotropic Drugs

Psychotropic drugs act in one way or another on the process of chemical signaling, a mechanism employed by the brain for the purposes of communication between neurones. Neurones make connection with each other at specialized regions of the cell membrane called synapses. Chemical transmission at synapses occurs when a chemical messenger or neurotransmitter is released from one neurone and interacts with a specific binding site or receptor on an adjacent neurone. In general, psychotropic drugs act to increase or decrease the impact of a neurotransmitter on its receptor. This can be achieved in a number of ways (Table 2).

Much is known about the pharmacological effects of psychotropic drugs in experimental animal studies. However, it is much less clear how such pharmacological changes are translated into therapeutic benefit in patients with psychiatric disorders. Studies in healthy volunteers may not be helpful in elucidating this issue. For example, a therapeutic course of an antidepressant drug has no effect on the mood of an individual who is not depressed. A further complication is that most psychotropic drugs take a number of weeks before their full clinical effect becomes apparent (Table 2). From this it has been deduced that the therapeutic effect of drug treatment is likely to be due to slowly evolving adaptive changes in neurotransmitter mechanisms and the neuronal circuits that depend on them. (A review of the mechanisms of drug action is given by Stahl 1996.)

When a patient has responded to psychotropic drug treatment it is usual for drug therapy to be continued for some time. Where a disorder is believed to run a self-limiting course, for example a single uncomplicated episode of major depression, it is customary to withdraw

Table 2 Mechanism of action of some psychotropic drugs and time to onset of therapeutic effect.

Drug	*Action*	*Time to onset of action*
Antidepressant	Increase action of noradrenaline and serotonin	2–4 weeks
Antipsychotic	Block dopamine receptors	2–6 weeks
Anxiolytic (benzodiazepine)	Increase action of γ-aminobutyric acid	immediate
Lithium	Decrease activity of receptor-linked enzyme systems	2–4 weeks (mania)

treatment after about six months. However, many psychiatric disorders are persistent or highly recurrent, and here drug treatment may need to be continued in the longer term.

Where circumstances are favorable it is often worthwhile trying to discontinue drug treatment, or at least lower the dose, while the patient is carefully monitored. In general, psychotropic drugs should not be discontinued suddenly because withdrawal symptoms may result. These are seen particularly with anxiolytic and antidepressant drugs. In addition, abrupt discontinuation of medication can sometimes result in "rebound" illness. For example, sudden withdrawal of lithium in patients with bipolar disorder confers a risk of mania of about 50% over the next six weeks (Goodwin, 1994). This is substantially greater than that which would be expected from the natural history of the illness.

6.06.1.3 Pharmacokinetics of Psychotropic Drugs

Before psychotropic drugs can produce their effects they need to reach the brain in adequate amounts. This depends on how well they are absorbed from the gastrointestinal tract into the blood stream and their ability to cross the blood–brain barrier. Subsequently, drugs are broken down or metabolized in the liver and then eliminated from the body in the urine by the kidney. Patients with liver or kidney disease can have exaggerated effects from small doses of drugs.

Plasma concentrations of drugs throughout the day vary, rising immediately after each dose and falling at a rate that differs between individual drugs and to some extent between individual people. However, this rate of decline influences how long the drug persists in the body.

The concept of plasma half-life is useful here. The half-life of a drug in plasma is the time taken for its concentration to fall by a half, once dosing has ceased. With most psychotropic drugs, the amount eliminated over time is proportional to plasma concentration and in this case it will take approximately five times the half-life for the drug to be eliminated from plasma. Equally, when dosing with a drug begins, it will take five times the half-life for the concentration in plasma to reach a steady state.

This can be important when planning treatment. For example, monoamine oxidase inhibitors (MAOIs) should not be given with selective serotonin reuptake inhibitors (SSRIs) because of the danger of drug interaction (see Section 6.06.7.4.5). If, for example, a patient is taking sertraline which has an elimination half-life of about 26 hours, it will be important to leave at least five times the half-life (a week is recommended) before starting MAOI treatment. When sertraline treatment begins, the plasma concentrations will continue to rise for about a week before reaching steady state.

Most psychotropic drugs have fairly long half-lives and once or twice daily dosing is sufficient. This aids compliance. Some antipsychotic preparations are made in the form of long-acting intramuscular preparations. These depot injections may need only to be given only once or twice monthly, which again has advantages in terms of compliance for some patients.

6.06.1.4 Prescribing Psychotropic Drugs

It is good practice to use well-tried drugs with therapeutic actions and side effects that are clearly understood. When a drug is prescribed it is necessary to determine the dose, the interval between doses and the likely duration of treatment. Until a clinician is thoroughly familiar with a drug it is important to consult the manufacturer's literature or other appropriate reference to decide the dosing schedule. Particular care should be taken to assess the possibility of drug interaction because many patients will be taking more than one kind of medicine.

Before providing a prescription the clinician should explain what effects are likely to be expected on first taking the drug, for example, drowsiness or dry mouth with a tricyclic antidepressant. They should also explain how long it will be before therapeutic effects will appear and what signs a patient should look for.

Many patients do not take their prescribed medication either because they do not perceive the need to take it or have fears about the possible consequences if they do. Time spent in discussing patient's concerns is well spent and is likely to improve compliance with medication. Written instructions (which are now often provided as inserts to drug packaging) can be a valuable adjunct.

There are special problems about prescribing in pregnancy because of the risk that drugs might produce adverse effects on fetal development (teratogenesis). Withdrawal symptoms in the new-born may also occur. Where possible, therefore, psychotropic drugs should not be prescribed to women who are pregnant or who are considering becoming pregnant. Where drug treatment is strongly indicated, for example, in a psychotic illness or with severe depression, a careful clinical risk benefit assessment should be made and discussed with the patient. It is usually possible to select preparations that appear on current evidence to be unlikely to produce terratogenic effects.

6.06.2 CLASSIFICATION OF DRUGS USED IN PSYCHIATRY

Psychotropic drugs are those whose main clinical effect is to produce a change in the psychological state. Psychotropic drugs used in psychiatry are conventionally divided into different classes, but the therapeutic actions of particular compounds are not confined to one diagnostic category. For example, SSRIs are classified as antidepressants and are effective in the treatment of major depression, but they also produce useful therapeutic effects in panic disorder, obsessive compulsive disorder and social phobia (Cowen, 1997). This breadth of effect does not mean that the latter syndromes are forms of depression. It merely emphasizes that the neuropsychological consequences of facilitating brain serotonin function may provide beneficial effects in a variety of psychiatric disorders.

Although there is considerable understanding of the pharmacological actions of psychotropic drugs, little is known about the neuropsychological consequences of these pharmacological actions and about the ways in which neuropsychological changes are translated into clinical benefit in different diagnostic syndromes. At present, therefore, the best plan is to classify drugs according to their major therapeutic use but to bear in mind therapeutic effects of different classes of drugs may overlap (Table 3).

These groups of drugs will be discussed in turn. Subsequently, general advice will be given about the use of psychotropic drugs in different psychiatric disorders and how they may be combined with psychological methods of treatment.

6.06.3 ANXIOLYTIC DRUGS

Anxiolytic drugs are indicated in the treatment of anxiety disorders. It must be remembered, however, that the classification of anxiety disorders in the *Diagnostic and statistical manual of mental disorders* (4th ed., *DSM-IV*) and the *International classification of diseases* (10th ed., *ICD-10*) subsumes a number of different disorders, some of which have a distinct drug response. For example, although benzodiazepines are effective in generalized anxiety disorder and to some extent in panic disorder, they are not useful in the treatment of obsessive compulsive disorder (Jenike, 1992).

Anxiolytic drugs are prescribed widely and often inappropriately. There is evidence, however, that this trend may be subsiding (Tyrer, 1997). To some extent this may reflect substitution of antidepressant drugs for benzodiazepines, since the former are effective in the treatment of anxiety disorders and may be less likely to cause dependence.

6.06.3.1 Benzodiazepines

6.06.3.1.1 Pharmacology

Benzodiazepines are anxiolytic, sedative, and in larger doses hypnotic. They also have muscle relaxant and anticonvulsant properties. Their pharmacological actions are mediated through specific receptor sites, located in a supramolecular complex with γ-aminobutyric acid (GABA) receptors. Benzodiazepines enhance GABA neurotransmission, thereby altering indirectly the activity of many other neurotransmitters, for example, noradrenaline and serotonin (Stahl, 1996).

6.06.3.1.2 Compounds available

Many different benzodiazepines are available. They differ both in the potency with which they interact with a benzodiazepine receptor, and in their plasma half-life. In general, high potency benzodiazepines and those with short half-lives are more likely to be associated with dependence and withdrawal. Benzodiazepines with short half-lives (less than 12 hours) include lorazepam and temazepam. Because of problems with dependence, long-acting compounds are preferable for the management of anxiety, even if such treatment is to be given intermittently and on an as-required basis. The long-acting benzodiazepines include drugs such as diazepam and chlordiazepoxide.

Table 3 Classification of clinical psychotropic drugs.

Class of drug	*Examples of classes*	*Indications*
Antipsychotic	Phenothiazines, Butyrophenones, Dibenzazepine	Acute treatment of schizophrenia and mania; prophylaxis of schizophrenia
Antidepressant	Tricyclic antidepressants MAOIs SSRIs SNRIs	Major depression (acute treatment and prophylaxis); anxiety disorders; obsessive-compulsive disorder (SSRIs)
Mood stabilizer	Lithium, Carbamazepine, Valproate	Acute treatment of mania; prophylaxis of recurrent mood disorder
Anxiolytic	Benzodiazepines, azapirones (buspirone)	Generalized anxiety disorder
Hypnotic	Benzodiazepines, Cyclopyrrolones (zopiclone), imidazopyridine (zolpidem)	Insomnia

Diazepam is rapidly absorbed, and can be used both for continuous treatment of anxiety and for treatment as required. Alprazolam, a high-potency and long-acting benzodiazepine, is used widely outside the UK for the treatment of panic disorder. This therapeutic efficacy is not confined to alprazolam, however, because equivalent doses of other high-potency agents, such as clonazepam, are also effective (Nutt & Bell, 1997). Flumazenil is a benzodiazepine receptor antagonist. This drug produces little pharmacological effect by itself but blocks the action of other benzodiazepines (Nutt, Cowen, & Little, 1982). It is therefore used to reverse acute toxicity of benzodiazepines, but carries a risk of provoking withdrawal symptoms in chronic users.

6.06.3.1.3 Adverse effects

Benzodiazepines are generally well tolerated. When they are given as anxiolytics, their main side effects are due to sedative properties that can lead to ataxia and drowsiness. A degree of cognitive impairment may be detectable, which is obviously a matter of concern when people are driving or operating machinery. The adverse effects of benzodiazepines are potentiated by alcohol. Although in some circumstances benzodiazepines may lower tension and aggression, in some people they can increase aggressive behavior, probably through disinhibition (Cowdrey & Gardner, 1988). They should therefore be prescribed only with great caution to those with a previous history of impulsive aggressive behavior.

It is now generally agreed that physical dependence develops after prolonged use of benzodiazepines. The frequency depends on the drug and the dosage, and has been estimated at between 5% and 50% among patients taking the drugs for more than six months. Although escalation during treatment is unusual, problems can appear when patients try to discontinue their medication, whereupon a withdrawal syndrome becomes apparent. This is characterized by anxiety, insomnia, nausea, and tremor, together with perceptual disturbances (Pertursson & Lader, 1984; Tyrer, 1997).

Withdrawal symptoms generally begin within 2–3 days of stopping a short-acting benzodiazepine, or within about seven days of stopping a longer-acting one. The symptoms generally last for 3–10 days. If benzodiazepines have been taken for a long time, it is best to withdraw them gradually over several weeks under supervision (Tyrer, Rutherford, & Huggett, 1981). Despite this, a few patients either cannot discontinue their benzodiazepines satisfactorily or are troubled by persistent long-standing withdrawal symptoms for long periods of time after the drugs have been discontinued.

6.06.3.2 Azapirones

The only drug in this class currently marketed for the treatment of anxiety is buspirone. This drug has no affinity for benzodiazepine receptors but stimulates a subtype of serotonin receptor called the serotonin-1A receptor. This receptor is found in high concentration in the raphe nuclei in the brain stem, where it regulates the firing of serotonin cell bodies. Administration of buspirone lowers the firing rate of serotonin neurones and thereby decreases serotonin neurotransmission in certain brain regions. This action may be the basis of its anxiolytic effects (Yocca, 1990).

Buspirone is different to benzodiazepines in that its anxiolytic effects take several days to develop, whereas those of benzodiazepines are apparent very quickly. Its side effect profile also differs; for example, it is associated with lightheadedness, nervousness, and headache early in treatment. There is little evidence that tolerance and dependence occur during buspirone use, although such judgment must always be made with circumspection. There is some evidence that patients who have previously responded to treatment with benzodiazepines do not respond well to buspirone. Buspirone cannot be used to treat benzodiazepine withdrawal. Although buspirone appears to be effective in the treatment of generalized anxiety disorder, current evidence does not suggest that it confers benefit in the treatment of panic disorder (Cowen, 1992).

6.06.3.3 Other Drugs Used to Treat Anxiety

6.06.3.3.1 Antidepressant drugs

Antidepressants usually ameliorate the anxiety that accompanies depressive disorders. In addition, tricyclic antidepressants and trazodone have been shown to be as effective as benzodiazepines in the management of generalized anxiety and panic disorder (Rickels, Downing, Schweizer, & Hassman, 1993). SSRIs and MAOIs are also effective in the treatment of panic disorder, but the selective noradrenaline reuptake inhibitor, maprotiline, is not (Den Boer & Westenberg, 1988).

6.06.3.3.2 Antipsychotic drugs

These drugs are sometimes prescribed for their anxiolytic effect. They are not more effective than benzodiazepines, but may have a place in the group of patients who have become irritable and disinhibited with benzodiazepines.

6.06.3.3.3 β-Adrenoceptor antagonists

These include drugs such as propanolol which are used to treat hypertension. Such drugs relieve some of the autonomic (peripheral) symptoms of anxiety, such as tachycardia and tremor, by blocking peripheral β-adrenoceptors. In general they are not particularly helpful in the treatment of patients with anxiety disorders, but can be helpful in otherwise healthy subjects who develop marked autonomic symptoms coupled to performance anxiety.

6.06.4 HYPNOTIC DRUGS

Hypnotic drugs are used to improve sleep. The benzodiazepine drugs described previously are widely used as hypnotics. Most hypnotics in common use act at the benzodiazepine GABA receptor complex; this includes more recently introduced compounds such as zolpidem and zopiclone. Occasionally, low-dose tricyclic antidepressants are used as hypnotics because of their sedating effects. Similarly, sedating antihistamines such as chlopheniramine have been employed to promote sleep.

Hypnotic drugs have two major problems; first, the development of tolerance, with rebound insomnia when medication is discontinued; and second, hangover effects that can compromise psychological performance the next day.

6.06.4.1 Compounds Available

The most commonly used hypnotics are benzodiazepines with short half-lives, such as temazepam and lormetazepam. However, there is increasing use of nonbenzodiazepine drugs such as zopiclone, a cyclopyrrolone, and zolpidem, an imidazopyridine. With these shorter-acting compounds daytime hangover is less common but is still experienced by some patients.

Both zopiclone and zolpidem bind to a site close to the benzodiazepine receptor, thereby facilitating brain GABA function. Zopiclone and zolpidem produce fewer changes in sleep architecture than benzodiazepines, and are also claimed to be less liable to produce tolerance and dependence (Langtry & Benfield, 1990). This has not yet been fully substantiated. The most common side effect of zopiclone is a bitter after-taste following injection, but behavioral disturbances including confusion, amnesia, and depressed mood have been reported. Zolpidem has also been associated with behavioral disturbances but more commonly causes nausea and dizziness.

Other hypnotic drugs include chloral hydrate and chlormethiazole. The latter has a short half-life and is commonly used to facilitate sleep in the elderly. In addition, in some countries, chlormethiazole is used to prevent withdrawal symptoms in patients dependent on alcohol. For this reason it is sometimes thought, mistakenly, to be a suitable hypnotic for alcoholic patients. In fact, chlormethiazole has barbiturate-like actions and can cause respiratory depression when combined with alcohol or in overdose.

6.06.5 ANTIPSYCHOTIC DRUGS

This term is applied to drugs that reduce psychomotor overactivity and diminish symptoms of psychosis. Alternative terms for these drugs are neuroleptic and major tranquilizer. None of these names is wholly satisfactory. Neuroleptic refers to the side effects rather than to the therapeutic effects of the drugs, and major tranquilizer does not refer to the most important clinical action, that of ameliorating the symptoms of psychosis. Therefore, the term antipsychotic drug is preferred here.

The main therapeutic uses of antipsychotic drugs are to reduce hallucinations, delusions, agitation, and psychomotor excitement in schizophrenia, mania, or psychosis secondary to a medical condition. The drugs are also used prophylactically to prevent relapse of schizophrenia and occasionally mania (Gelder, Gath, Mayou, & Cowen, 1996).

6.06.5.1 Pharmacology

Antipsychotic drugs share the property of blocking brain dopamine receptors. Dopamine receptors are of several biochemical subtypes, but most antipsychotic drugs bind strongly to dopamine-D_2 receptors, and this action appears to account both for their antipsychotic activity and their propensity to cause movement disorders.

Actions at other neurotransmitter receptors may offset the liability of D_2 receptor antagonists to produce movement disorders. For example, thioridazine is a potent antagonist at muscarinic cholinergic receptors, and anticholinergic drugs are known to possess anti-Parkinsonian effects. This might account for the diminished liability of thioridazine to cause movement disorders. Similarly, the lack of movement disorders associated with risperidone and olanzapine has been attributed to the ability of these drugs to block serotonin_2 receptors as well as D_2 receptors (see Stahl, 1996).

6.06.5.2 Compounds Available

A large number of antipsychotic compounds have been developed. The main distinction of clinical utility is into typical and atypical antipsychotics. Atypical antipsychotics are so called because they have a decreased likelihood to cause extrapyramidal side effects or movement disorders.

6.06.5.2.1 Typical antipsychotics

These drugs have comparable efficacy in the treatment of psychosis but different side effect profiles because of their other pharmacological properties. For example, phenothiazines such as chlorpromazine and thioridazine are sedating and tend to lower blood pressure. They are, however, less likely to cause movement disorders than nonsedating phenothiazines, such as trifluoperazine and fluphenazine. The pharmacological profile of the thioxanthenes, such as flupenthixol and clopenthixol, resembles the nonsedating phenothiazines and the same is true of the butyrophenone, haloperidol.

A number of typical antipsychotic drugs (the decanoates of haloperidol, fluphenazine, flupenthixol and zuclopenthixol) are available as long-acting intramuscular depot preparations, given at intervals of 2–4 weeks. For many patients continued medication is the only way to prevent psychotic relapse. In some subjects compliance with medication is better if they will accept a long-acting intramuscular preparation.

Another intramuscular preparation is zuclopenthixol acetate whose action lasts for 1–2 days. This preparation can be useful in an acutely psychotic patient where antipsychotic medication is needed but where oral drug administration is ineffective or not possible. The disadvantage of this approach is that it is not easily possible to titrate the dosage of medication for an individual patient (Royal College of Psychiatrists, 1993).

6.06.5.2.2 Atypical antipsychotic drugs

These include a number of compounds that differ strikingly in their structure and pharmacological properties. Sulpiride is a D_2 receptor blocker, but it appears to act more selectively on D_2 receptors on mesolimbic and mesocortical regions than on those in the basal ganglia. This might account for its reduced liability to cause extrapyramidal side effects. In contrast, risperidone is a potent D_2 receptor antagonist but is even more potent at blocking serotonin_2 receptors. Concomitant serotonin_2 receptor blockade is believed to attenuate the movement disorders caused by unnopposed D_2 receptor antagonism (Livingston, 1994).

Olanzapine and sertindole are also serotonin_2 receptor antagonists but have less effect than risperidone on D_2 receptors. Both these factors may account for their decreased liability to cause movement disorders (Gerlach & Peacock, 1995; Reus, 1997). In addition, it has been claimed that risperidone, olanzepine, and sertindole are more effective than typical antipsychotics, particularly having some activity against so-called negative symptoms of schizophrenia, which are difficult to treat pharmacologically (Marder & Meibach, 1994; Tollefson & Sanger, 1997). These claims are currently being tested but clinically risperidone and olanzepine are being used increasingly in preference to typical antipsychotic drugs.

Clozapine is an important drug because it is the only drug with established efficacy in patients who are resistant to other antipsychotic treatments (Kane, Honigfeld, Singer, & Meltzer, 1988). Clozapine has complex pharmacology with weak binding to dopamine-D_2 receptors but strong antagonist properties at a variety of serotonin and noradrenergic receptors. Because of a rare but serious adverse effect on white blood cells, clozapine can be used only with special monitoring (see below).

6.06.5.3 Adverse Effects

6.06.5.3.1 Movement disorders

Probably the most troublesome side effect of antipsychotic drugs, particularly typical antipsychotics, are movement disorders, which are a consequence of D_2 receptor blockade in the basal ganglia. At least four different kinds of movement disorder are recognized: acute dystonia, akathisia (a Parkinsonian syndrome), and tardive dyskinesia (Table 4).

Acute dystonia occurs soon after treatment begins, especially in young men. It is observed most often with drugs such as haloperidol and trifluoperazine. The main features are caused by acute contraction of muscle groups, resulting in torticollis (neck twisting), tongue protrusion, grimacing and oculogyric crisis (rolling upward of the eyes). These symptoms are distressing and alarming for patients, and can be controlled by anticholinergic drugs, such as benztropine or a benzodiazepine.

Akathisia is an unpleasant feeling of physical restlessness, with a compelling need to move. Patients are usually very distressed by akathisia and can present in a state of severe agitation. It usually occurs in the first few weeks of treatment with antipsychotic drugs but may only begin after several months. Akathisia is not reliably treated by anticholinergic drugs, but may disappear when the dose of the antipsychotic agent is reduced. Some cases are helped by treatment with β-adrenoceptor antagonists, such as propranolol, and short-term benzodiazepine administration has also been employed.

The Parkinsonian syndrome caused by antipsychotic drugs presents with the usual clinical triad of akinesia, tremor, and muscular rigidity. These symptoms can be controlled by lowering the dose of the antipsychotic drug or with anticholinergic agents (see below).

The last syndrome, tardive dyskinesia, is particularly serious because, unlike the other extrapyramidal effects, it does not always recover when antipsychotic drugs are stopped. It is usually characterized by chewing and sucking movements of the lips and jaw, but can involve limbs and occasionally the whole body. Although this syndrome is seen occasionally among patients who have not taken antipsychotic drugs, clinical observations suggest it is much more common in those who have received antipsychotic agents for extended periods of time. Estimates of the frequency of the syndrome vary in different series, but it seems to develop in 20–30% of patients with schizophrenia treated with long-term antipsychotic drugs (Jeste & Caligiuri, 1993). Whatever the exact incidence, the risk of this syndrome should be a deterrent to the long-term prescription of antipsychotic drugs unless clearly indicated.

Many treatments for tardive dyskinesia have been tried but none is universally effective. The antipsychotic drug should be stopped if the state of the psychiatric illness allows this. About 50% of cases may then remit. Where this in not possible, increasing the dose of antipsychotic drug may produce some suppression of movement symptoms but this relief is usually temporary. Sulpiride, however, may provide rather more sustained benefit with few adverse effects. Interestingly, treatment with vitamin E has been found useful in some studies (Jeste & Caligiuri, 1993).

6.06.5.3.2 Autonomic and endocrine effects

Several of the antipsychotic drugs, particularly phenothiazines, such as chlorpromazine

Table 4 Some unwanted effects of antipsychotic drugs.

Effect	*Symptoms*
Movement disorders	Acute dystonia, akathisia, parkinsonism, tardive dyskinesia
Autonomic and endocrine effects	Dry mouth, constipation, urinary hesitancy, blurred vision, sedation, postural hypotension, hypothermia, amenorrhoea, galactorrhoea, decreased libido
Other	Cardiac arrhythmias, weight gain, agranulocytosis (clozapine)

and thioridazine, are antagonists at muscarinic cholinergic receptors. This leads to dry mouth, urinary hesitancy and retention, constipation, reduced sweating, blurred vision, and rarely the precipitation of glaucoma.

Phenothiazines, and risperidone also have strong antagonist activity at α_1-adrenoceptors. This leads to sedation, hypotension and sexual dysfunction. Antipsychotic drugs that block histaminic and some subtypes of serotonin receptors can cause troublesome weight gain. This can be a particular problem with chlopromazine, thioridazine, clozapine, and olanzepine.

Blockade of D_2 receptors elevates plasma prolactin levels which can cause amenorrhoea and galactorrhoea in women and loss of libido in both sexes. The atypical antipsychotic drugs, with the exception of risperidone and sulpiride appear to have less effect on plasma prolactin.

6.06.5.3.3 Neuroleptic malignant syndrome

This rare but serious disorder occurs in a small minority of patients taking antipsychotic drugs, particularly high-potency compounds. Most reported cases have followed the use of antipsychotic drugs for schizophrenia, but in some cases the drugs were used for mania, depressive disorder, and psychosis secondary to a medical condition. The clinical picture includes the rapid onset, over 24–72 hours, of severe motor, cognitive, and autonomic disorders. The prominent motor symptom is generalized rigidity. The psychological symptoms include mutism, stupor, or fluctuating levels of consciousness. Hyperpyrexia develops with evidence of autonomic instability in the form of rapidly changing blood pressure, tachycardia, excessive sweating and urinary incontinence. Plasma levels of the enzyme, creatinine phosphokinase, are increased to very high levels. The neuroleptic malignant syndrome has a significant mortality, which may be declining but is probably still about 10%. The syndrome lasts for 1–2 weeks after stopping an oral neuroleptic, but may last 2–3 times longer after stopping long-acting preparations. Patients who survive usually make a complete recovery but residual movement disorders are sometimes seen (Addonizio & Susman, 1991).

The mainstay of treatment in neuroleptic malignant syndrome is symptomatic, with support in an intensive care unit if needed. No drug treatment is of definite utility. The dopamine receptor agonist, bromocriptine, is often tried, but there is no definite evidence of effectiveness. Patients who have developed neuroleptic malignant syndrome may need in the future to be treated with antipsychotic drugs. At least two weeks should elapse before antipsychotic treatment is reinstated, and it is prudent to start treatment cautiously with an oral low potency drug such as thioridazine.

6.06.5.3.4 Other adverse effects

A rare adverse effect, but one which is of particular concern, is the development of cardiac arrhythmias. Subclinical electrocardiogram (ECG) changes are not uncommon and usually take the form of prolongation of the QT interval. This appears to be more problematic with some drugs than others, for example, pimozide and sertindole, where the use of ECG monitoring has been recommended. It should also be noted that most antipsychotic drugs appear to lower the seizure threshold to some extent, so must be used with caution in patients with a tendency to seizure disorder.

Typical antipsychotic drugs have not been shown to be teratogenic, but nevertheless should be used cautiously in early pregnancy. There is presently insufficient data on the possible teratogenic effects of the atypical antipsychotic drugs.

6.06.5.3.5 Adverse effects of clozapine

As noted above, the use of clozapine requires special monitoring with regard to blood white cell count. For this reason both the hematological and other adverse effects of clozapine will be discussed here.

The use of clozapine is associated with a significant risk of leucopenia (about 2–3%) which can progress to agranulocytosis (Krupp & Barnes, 1992). Weekly blood counts for the first 18 weeks of treatment and at two week intervals thereafter are mandatory. With this intensive monitoring the early detection of leucopenia can be followed by immediate withdrawal of clozapine and reversal of the low white cell count. This procedure greatly reduces, but does not eliminate, the risk of progression to agranulocytosis. It is usually recommended that clozapine be used as the sole antipsychotic agent in a treatment regimen. Clearly, it is wise to avoid concomitant use of drugs such as carbamazepine, which may also lower the white cell count.

Because of its relatively weak blockade of dopamine D_2 receptors, clozapine is less likely than other antipsychotic drugs to cause extrapyramidal movement disorders. It does not increase plasma prolactin, hence galactorrhoea does not occur. However, its use is associated with hypersalivation, drowsiness, postural hypotension, weight gain, and hyperthermia. Seizures may occur at higher doses. Rarely, myocarditis has been reported.

6.06.5.4 Dosage of Antipsychotic Drugs

Doses of antipsychotic drugs need to be adjusted for the individual patient and changes should be made gradually. There is a growing trend for lower doses to be recommended. This is based in part on recent studies with positron emission tomography which have demonstrated that adequate dopamine D_2 receptor blockade can be obtained with low doses of conventional antipsychotic drugs, for example, 5 mg a day of haloperidol (Farde, Wiesel, & Nordstrom, 1989) (Table 5). Such doses produce an adequate antipsychotic effect in the majority of patients. Higher doses may cause further calming but are also likely to be associated with significant adverse effects, some of which may be serious, for example, cardiac arrhythmias. A view of growing influence is that the combination of modest doses of antipsychotic drugs with a benzodiazepine is a safer and more effective means of producing rapid sedation than high doses of antipsychotic drugs (Pilowsky, Ring, Shine, Battersby, & Lader, 1992).

The association of sudden unexplained death with antipsychotic drug treatment is a matter of continuing debate. For example, it is not established whether the rate of such deaths is greater in patients receiving antipsychotic drugs than in those receiving other treatments, or whether the rate in psychiatric patients is higher than in the general population. However, antipsychotic drugs are known to alter cardiac conduction (see above), and some drugs, such as chlorpromazine, also produce hypotension. Although the relationship between high doses of antipsychotic drug treatment and sudden death is not established, it is clearly prudent to use as low a dose of an antipsychotic drug as the clinical circumstances permit (Royal College of Psychiatrists, 1993).

6.06.6 ANTI-PARKINSONIAN DRUGS

Although these drugs have no direct therapeutic use in psychiatry, they are often required to control the extrapyramidal side effects of antipsychotic drugs, particulary acute dystonia and symptoms of Parkinsonism. They are of modest benefit in akathisia and actually worsen tardive dyskinesia. The pharmacological effect of these drugs is to block peripheral and central muscarinic cholinergic receptors.

6.06.6.1 Preparations Available

Many anticholinergic drugs are available and there is no reason for choosing one over the others for the treatment of neuroleptic induced movement disorders. Those most often used in psychiatric practice are benzhexol, benztropine, procyclidine, and orphenadrine. An injectable preparation of biperiden is useful for the treatment of acute dystonias.

Table 5 Daily dose of different antipsychotic drugs required to produce greater than 70% blockade of D_2 receptors in basal ganglia.

Drug	*Dose* (mg)
Chlorpromazine	200
Thioridazine	300
Trifluoperazine	10
Haloperidol	4
Flupenthixol	10
Sulpiride	800

Source: Farde et al. (1989).

6.06.6.2 Adverse Effects

In large doses these drugs may cause an acute organic syndrome, particularly in the elderly. Their anticholinergic activity can summate with those of antipsychotic drugs so that glaucoma or retention of urine in men with enlarged prostates may be precipitated. Drowsiness, dry mouth and constipation also occur. These effects tend to diminish as the drug is continued. Anticholinergic drugs can also exacerbate tardive dyskinesia but are probably not a predisposing factor in its development. Anticholinergic drugs can also be abused for their euphoriant and psychomimetic effects at high doses.

6.06.7 ANTIDEPRESSANTS

Antidepressant drugs are indicated in the treatment of major depression and dysthymia. Certain antidepressants are also effective in the treatment of anxiety disorders, and the eating disorder bulimia nervosa. Currently used antidepressant drugs can be divided into three main classes, depending on their acute pharmacological properties. The first class consists of compounds that inhibit the reuptake of noradrenaline and/or serotonin. This class includes the tricyclic antidepressants and the SSRIs. The second class consists of drugs that inhibit the enzyme MAO. The third class consists of drugs with complex effects on monoamine mechanisms, for example, mianserin and nefazodone, which cannot be easily categorized under the first two headings.

In the broad range of major depression, these drugs are of equivalent efficacy. The main distinctions between them are in their adverse effects, toxicity, and cost (Table 6). These three classes of drugs will be considered in turn after some comments on the possible mechanism of action of antidepressants.

6.06.7.1 Mechanism of Action

The primary pharmacological action of reuptake inhibitors and MAOIs can be detected within hours of the start of treatment, and yet the antidepressant effects of drug therapy can be delayed for a number of weeks. For example, it has been suggested that 4–6 weeks should elapse before an assessment of the effect of an antidepressant drug can be made in an individual patient (Depression Guideline Panel, 1993; Quitkin et al., 1996).

In animal experimental studies, the acute effect of antidepressants to facilitate noradrenaline and serotonin neurotransmission is followed by numerous secondary adaptive changes in noradrenaline and serotonin pathways. It is thought that it is these neuroadaptive changes that lead to the clinical antidepressant effect, probably by further enhancing the acute potentiation that antidepressant drugs produce on noradrenaline and serotonin neurotransmission (Blier & Montigny, 1994; Svensson & Usdin, 1978).

An important action observed in animal experimental studies following repeated administration of antidepressant drugs is a gradual desensitization of inhibitory autoreceptors on serotonin and noradrenaline cell bodies. These receptors normally have the effect of decreasing the firing of these cells, and hence their desensitization would be expected to add to the facilitation of neurotransmission produced by the antidepressant. Thus the clinical effects of antidepressant treatment may result from an increasing potentiation of noradrenaline and serotonin neurotransmission over time.

6.06.7.2 Tricyclic Antidepressants

6.06.7.2.1 Pharmacological properties

Tricyclic antidepressants have a three-ringed structure with an attached side chain. The first tricyclic to be introduced was imipramine, and there have been many modifications, so that a range of tricyclic compounds is now available. These can broadly be divided into tertiary and secondary amines, the distinction being that tertiary have a terminal methyl group on the side chain, whereas the secondary amines do not. In general, compared with the secondary amines, tertiary amines have a higher potency to block the serotonin reuptake site and are stronger antagonists of noradrenaline α_1-adrenoceptors and muscarinic cholinergic receptors. Therefore, in clinical use tertiary amines are more sedating and cause more anticholinergic side effects than secondary amines. In the UK, tertiary amines such as amitriptyline, dothiepin, and imipramine are popular in the treatment of depression, whereas in the USA secondary amines such as desipramine and nortriptyline are more commonly used.

Antidepressant drugs also antagonize histamine H_1 receptors, which can cause drowsiness and weight gain. Tricyclics also have quinidine-like membrane stabilizing effects. This may explain why they impair cardiac conduction and cause high toxicity in overdose.

6.06.7.2.2 Adverse effects of tricyclic antidepressants

The adverse effects of tricyclic antidepressants can, in general, be derived from their receptor blocking properties (Table 7). As mentioned above, anticholinergic and antiadrenergic effects are common. In addition, the drugs can cause tiredness and drowsiness, although secondary amines, such as desipramine, can cause insomnia. Fine tremor and muscle twitching have been observed and like

Table 6 Side effect profiles of some antidepressant drugs.

Drug	*Anticholinergic*	*Sedation*	*Insomnia*	*Cardiotoxic*	*Nausea/vomiting*
Amitriptyline	+ + +	+ + +	0	+ + +	0
Desipramine	+ +	+	+	+ + +	0
Lofepramine	+ +	+	+	0	0
Trazodone	0	+ + +	0	+	+ +
Nefazodone	0	+	0	0	+ +
Mirtazapine	0	+ + +	0	0	0
SSRIs	0	0/+	+ +	0	+ + +
SNRI	0	0/+	+ +	0	+ + +

0 = not present; + + + = strong.

antipsychotic drugs, tricyclic antidepressants lower the seizure threshold, which means they must be used with caution in people predisposed to seizure disorders. Allergic skin rashes, cholestatic jaundice, and agranulocytosis, are seen rarely. Weight gain and sexual dysfunction are more common.

Sudden withdrawal of tricyclics can produce an abstinence syndrome, characterized by nausea, anxiety, sweating, and insomnia. Current evidence does not suggest that tricyclics such as amitriptyline and imipramine are important human teratogens. There is less data about other tricyclic antidepressants.

In overdose, tricyclic antidepressants produce a large number of effects, of which some are extremely serious. Therefore urgent expert treatment in a general hospital is required. The main danger comes from cardiovascular effects, which include cardiac arrhythmias with ventricular fibrillation. In addition, respiratory depression can occur, and the resulting hypoxia increases the likelihood of cardiac complications. Tricyclics delay gastric emptying, and so gastric lavage is valuable for several hours after the overdose.

6.06.7.2.3 Amoxapine

Some tricyclics have pharmacological properties sufficiently distinct to be worth separate mention. Amoxapine is a fairly selective inhibitor of noradrenaline uptake but, unusually for a tricyclic antidepressant, produces significant blockade of dopamine D_2 receptors. The combined effect of amoxapine to increase noradrenaline neurotransmission and antagonize D_2 receptors has led to suggestions that this compound may be particularly useful in the treatment of depressive psychosis when combined treatment with antidepressant and antipsychotic drugs is often required. However, the use of a single preparation to produce combined pharmacological effect limits prescribing flexibility. Furthermore, as might be expected, the D_2 receptor blocking properties of amoxapine may result in extrapyramidal disorders (Rudorfer & Potter, 1980).

6.06.7.2.4 Clomipramine

Clomipramine is the most potent of the tricyclic antidepressants in inhibiting the reuptake of serotonin. Probably because of this, unlike other tricyclic antidepressants, clomipramine is useful in treating the symptoms of obsessive compulsive disorder whether or not there is a coexisting major depression (Jenike, 1992). Clomipramine is also available as an intravenous infusion, but in general this form of administration does not appear to produce better therapeutic effects than the oral route.

6.06.7.2.5 Lofepramine

Lofepramine is a fairly selective inhibitor of noradrenaline reuptake, and has fewer anticholinergic and antihistaminic properties than amitriptyline. It has been widely compared with other tricyclic antidepressants, and in general its antidepressant efficacy is equivalent. Lofepramine is not sedating; early in treatment it can be experienced as activating, an effect which some depressed patients find unpleasant. Similarly, impaired sleep does not usually improve until the underlying depression remits. The most important feature of lofepramine is that in overdose it is not cardiotoxic and it is therefore much safer than conventional tricyclic antidepressants. Therefore lofepramine is likely to be safer than other tricyclics for patients with cardiovascular disease, although caution is still required (Lancaster & Gonzalez, 1990).

Table 7 Some adverse effects of tricyclic antidepressants.

Pharmacological action	*Adverse effect*
Anticholinergic	Dry mouth, tachycardia, blurred vision, glaucoma, constipation, urinary retention, cognitive impairment
Antiadrenergic	Drowsiness, postural hypotension, sexual dysfunction
Histamine H_1 receptor blockade	drowsiness, weight gain
Other	Cardiac conduction defects, cardiac arrhythmias, epileptic seizures, (all common in overdose), rash, oedema, sweating, low white cell count (rare)

6.06.7.2.6 Maprotiline

Maprotiline is often referred to as a quadricyclic antidepressant because the tricyclic nucleus is supplemented by an ethylene bridge across the middle ring. It is the most selective noradrenaline uptake inhibitor of the tricyclic antidepressants currently available, but has moderate antihistaminic properties and rather less anticholinergic effects than imipramine. It appears as effective as reference tricyclics. The use of maprotiline at doses above 200 mg daily have been associated with a higher incidence of seizures than is usual during tricyclic treatment. Therefore a dose range of 75–150 mg daily has been recommended, and the coprescription of other drugs that may lower the seizure threshold, such as phenothiazines, should be approached with caution. Maprotiline has effects on the heart that are similar to those of conventional tricyclics, and in overdose it is at least as toxic (Rudorfer & Potter, 1989).

6.06.7.3 Selective Serotonin Reuptake Inhibitors

6.06.7.3.1 Pharmacological properties

Five SSRIs, citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline, are available at present for clinical use in the UK. SSRIs are a structurally diverse group, but they all inhibit the reuptake of serotonin with a high potency and selectivity. None of them has an appreciable affinity for the noradrenaline uptake site, and present data suggest that they have a low affinity for other monoamine neurotransmitter receptors (Stahl, 1996).

6.06.7.3.2 Efficacy in depression

The SSRIs have been extensively compared with placebo and with reference tricyclic antidepressants. The SSRIs are all clearly superior to placebo and are generally as effective as tricyclics antidepressants in the treatment of major depression. Most comparative studies have been of moderately depressed outpatients, and there has been concern that SSRIs may be less effective than conventional tricyclic antidepressants for more severely depressed patients. This is based to some extent on the work of the Danish University Antidepressant Group (1990), who found that the tricyclic clomipramine is significantly more effective than either paroxetine or citalopram in depressed inpatients. In addition, more recent meta-analyses have suggested that SSRIs may be slightly less effective than drugs that potently block the reuptake of both serotonin and noradrenaline. This categorization includes clomipramine and the new antidepressant, venlafaxine (Anderson, 1997) (see below).

6.06.7.3.3 Unwanted effects of SSRIs

The SSRIs have a different side effect profile to tricyclic antidepressants and are somewhat better tolerated at therapeutic dosage (Table 8). In meta-analyses against conventional tricyclic antidepressants the drop-out rate due to adverse effects with SSRIs is about 25% less. Whether this confers significant cost benefit is controversial.

The SSRIs are less cardiotoxic than tricyclic antidepressants and are safer in overdose. They also lack anticholinergic effects and are less sedating. Their adverse effect profile consists mainly of gastrointestinal symptoms and central nervous system effects. Sexual dysfunction is also common, occurring in up to about 25% of people. A rare but problematic side effect, more frequent in the elderly, is a low sodium state. They can rarely cause movement disorders. Discontinuation of paroxetine and sertraline

Table 8 Some side effects of SSRIs.

Effect	*Symptoms*
Gastrointestinal	Common: nausea, appetite loss, dry mouth, diarrhea, constipation, dyspepsia Uncommon: vomiting, weight loss
Central nervous system	Common: headache, insomnia, dizziness, anxiety, fatigue, tremor, somnolence Uncommon: extrapyramidal reaction, seizures
Other	Common: sweating, delayed orgasm, anorgasmia Uncommon: rash, pharyngitis, dyspnoea, serum sickness, hyponatremia, alopecia

has been associated with a withdrawal syndrome consisting of nausea, irritability, impaired sleep and ataxia (Cowen, 1996).

It is not clear whether SSRIs are human teratogens. Fluoxetine may increase rates of premature delivery and perhaps minor fetal abnormalties, but this is controversial (Chambers, Johnson, & Dick, 1996; Robert, 1996).

6.06.7.4 Monoamine Oxidase Inhibitors

MAOIs were introduced just before the tricyclic antidepressants, but their use has been less widespread because of both troublesome interactions with foods and drugs and uncertainty about their therapeutic efficacy. Recent controlled studies have shown that in adequate doses MAOIs are useful antidepressants, often producing clinical benefit in depressed patients who have not responded to other medications or electroconvulsive therapy (ECT). In addition, MAOIs can be useful in refractory anxiety states (Nutt & Glue, 1989; Paykel, 1990). These beneficial effects have to be weighed against the need to adhere to strict dietary and drug restrictions in order to avoid reactions with tyramine and other sympathomimetic agents. In practice this means that MAOIs are very rarely used as first-line treatment. It remains to be seen whether this approach will be altered by the recent availability of MAOIs, such as moclobemide, that do not potentiate tyramine.

6.06.7.4.1 Pharmacology

The MAOIs inactivate enzymes that oxidize noradrenaline, serotonin, tyramine, and other amines that are widely distributed in the body as transmitters, or are taken in food and drink or as drugs. Monoamine oxidase (MAO) exists in a number of forms that differ in their substrate and inhibitor specificities. From the point of view of psychotropic drug treatment it is important to recognize that there are two forms of MAO (type A and type B), encoded by separate genes. In general, MAO-A metabolizes intraneuronal noradrenaline and serotonin, whereas both MAO-A and MAO-B metabolize dopamine and tyramine.

6.06.7.4.2 Compounds available

Phenelzine is the most widely used and widely studied compound. Isocarboxazid is reported to have fewer side effects than phenelzine and can be useful for patients who respond to the latter drug but suffer from its side effects of hypotension or sleep disorder. Tranylcypromine differs from the other compounds in combining the ability to inhibit MAO with an amphetamine-like stimulating effect. There are more reports of adverse drug and food reactions with tranylcypromine than other MAOIs, so it should be prescribed with particular caution.

Moclobemide is the most recently developed MAOI to be marketed. It differs from the other compounds in selectively binding to MAO-A, which it inhibits in a reversible way. This results in a lack of significant interactions with foodstuffs and a quick offset of action (see below).

6.06.7.4.3 Efficacy of MAOIs in depression

For many years MAOIs were in relative disuse because several studies, in particular a large controlled trial by the Medical Research Council, found them no better than placebo in the treatment of depressive disorders (Clinical Psychiatry Committee, 1965). It seems likely that the doses of MAOIs were too low in these early investigations; in the Medical Research Council study the maximum dose of phenelzine was 45 mg daily as against the current practice of doses up to 90 mg daily if side effects permit. In this wider dose range MAOIs are superior to placebo and generally equivalent to tricyclic antidepressants in their therapeutic activity (Paykel, 1990).

6.06.7.4.4 Unwanted effects

MAOIs have numerous unwanted effects (Table 9). In clinical practice the main problems are insomnia, weight gain, and postural hypotension. Ankle edema is also not uncommon. Phenelzine and isocarboxazid have been associated with hepatocellular jaundice. There are little data on the possible teratogenicity of MAOIs in humans.

6.06.7.4.5 Interactions with foodstuffs and drugs

Some foods contain tyramine, a substance that is normally inactivated by MAO in the liver and gut wall. When MAO is inhibited, tyramine is not broken down and is free to exert its hypertensive effects. These effects are due to release of noradrenaline with a consequent elevation in blood pressure. This may reach dangerous levels and may occasionally result in cerebrovascular accident. Important early symptoms of such a crisis include a severe and usually throbbing headache.

There have been reports of many foods being implicated in hypertensive reactions with MAOIs, but many of these have cited single cases and hence are of uncertain validity. Another complication is that the tyramine content of a particular food item may vary, as

Table 9 Adverse effects of MAOIs.

Effect	*Symptoms*
Central nervous system	Insomnia, drowsiness, agitation, headache, fatigue, weakness, tremor, mania, confusion
Autonomic	Blurred vision, difficulty passing urine, sweating, dry mouth, postural hypotension, constipation
Other	Sexual dysfunction, weight gain, peripheral neuropathy (rare), edema, rashes, hepatocellular toxicity (rare), leucopenia (rare)

may the susceptibility of an individual patient to a hypertensive reaction. If a forbidden food has been consumed on one occasion without adverse effects, this does not preclude a future reaction. It has been concluded that the following foods and drinks should be avoided (Davidson, 1992):

(i) all cheeses except cream, cottage, and ricotta cheeses;

(ii) red wine, sherry, beer, and liquors;

(iii) pickled or smoked fish;

(iv) brewer's yeast products, for example, Marmite, Bovril, and some packet soups;

(v) broad bean pods;

(vi) beef or chicken liver;

(vii) fermented sausage, for example, pepperoni, salami; and

(viii) unfresh, overripe, or aged food, for example, pheasant, venison, unfresh dairy products.

Despite this list, case reports suggest that cheese is the food most often incriminated in serious adverse reactions. Hypertensive reactions should be treated with parenteral administration of an α_1-adrenoceptor antagonist, such as phentolamine. Chlorpromazine can be used if the latter is not available. Oral nifedipine may also be useful. Whatever treatment is given, blood pressure must be monitored carefully.

A number of drugs cause serious interactions with MAOIs. In particular, drugs that increase brain serotonin function such as the SSRIs and clomipramine can cause a fatal neurotoxicity syndrome (Sternbach, 1991). In general medicine coadministration of opiate analgesics, particularly pethidine, can produce a similar effect. Finally, drugs that potentiate noradrenaline can cause serious hypertensive reactions. The importance of this is that such compounds are often present in "over-the-counter" cold and flu remedies. Patients receiving MAOI treatment must be warned not to take any other medication until its safety with MAOIs has been specifically checked.

6.06.7.4.6 Moclobemide

In its freedom from tyramine reactions, the reversible type A MAOI, moclobemide, has a clear advantage over conventional MAOIs (Simpson & De Leon, 1989). As with all new antidepressants, however, the therapeutic efficacy of moclobemide, particularly in severely ill patients is not as well established as that of phenelzine or tranylcypromine. Moreover, a recent meta-analysis suggested that it might be somewhat less effective than clomipramine and imipramine in depressed inpatients (Angst, Amrein, & Stabl, 1995).

Moclobemide is better tolerated than conventional MAOIs but can cause insomnia and nausea. Caution still has to be exercised when moclobemide is coprescribed with other drugs. It is recommended that it should not be prescribed with SSRIs or clomipramine because of the risk of serotonin syndrome (see above). As for the irreversible MAOIs, moclobemide may react adversely with opiates and noradrenaline potentiating drugs.

6.06.7.5 Other Antidepressant Drugs

Under this heading are discussed drugs whose mechanism of action cannot be easily grouped with tricyclic antidepressants, SSRIs, or MAOIs. These drugs also have differing adverse-effect profiles. They are therefore discussed individually below.

6.06.7.5.1 Mianserin

Mianserin is a quadricyclic compound with complex pharmacological actions. It has weak noradrenaline reuptake inhibiting effects, and is a fairly potent antagonist at a number of neurotransmitter receptors, including serotonin$_2$, serotonin$_3$, and noradrenergic α_1- and α_2-adrenoceptors. It is not a muscarinic cholinergic antagonist and is not cardiotoxic.

Controlled trials have shown that mianserin is superior to placebo in the management of depression, and comparative studies against imipramine and clomipramine have shown no difference in effect. These studies are difficult to assess because of the wide range of doses that have been used. Many early studies of mianserin used doses of 30–60 mg daily, whereas much higher doses of up to 200 mg daily have sometimes been advocated for inpatients (Montgomery, Bullock, & Pinder, 1991).

The main adverse effects of mianserin are drowsiness and dizziness. Significant cognitive impairment is more likely with mianserin than with SSRIs, and weight gain is a common problem. The most serious adverse effect of mianserin is a lowering of the white cell count, and fatal agranulocytosis has been reported. It is recommended that a blood count be obtained before starting mianserin treatment, and that the white cell count be monitored monthly for three months after treatment has started.

6.06.7.5.2 Mirtazapine

Mirtazapine is a new antidepressant which is structurally related to mianserin. Its pharmacological properties are similar but its noradrenergic α_1-adrenoceptor blockade is less potent which means that in practice it is a little less sedating. Placebo-controlled trials have shown an efficacy in the treatment of major depression, although the relative efficacy of mirtazapine against other antidepressants is not fully clear (Bruijn et al., 1996; Davies & Wilde, 1996).

Mirtazepine is generally well tolerated, with the most common side effects being drowsiness, dizziness, and weight gain.

6.06.7.5.3 Trazodone

Trazodone is a triazolopyridine derivative with complex actions on serotonin pathways. Studies *in vitro* suggest that trazodone has some weak serotonin reuptake inhibiting properties but these are probably not manifest during clinical use. Trazodone is an antagonist at serotonin$_2$ receptors but its active metabolite, *m*-chlorophenylpiperazine (*m*CPP), is a serotonin receptor agonist. Trazodone also blocks postsynaptic α_1-adrenoceptors, which gives it a distinct sedating profile.

Several placebo-controlled studies have shown that trazodone in doses of 150–600 mg is superior to placebo in the treatment of depressed patients. Trazodone also appears to have equivalent antidepressant activity to compounds such as imipramine. Many of these studies were carried out in moderately depressed outpatients, and the efficacy of trazodone in depressed inpatients is not as well established (Rudorfer & Potter, 1998)

The major unwanted effect of trazodone is excessive sedation, which can result in significant cognitive impairment. Nausea and dizziness are also reported, particularly if the drug is taken on an empty stomach. The α_1-adrenoceptor antagonist properties of trazodone may lower blood pressure to some extent, and postural hypotension has been reported. Trazodone is less cardiotoxic than conventional tricyclics, but there are reports that cardiac arrhythmias may be worsened in patients with cardiac disease. Nevertheless, trazodone is much less toxic in overdose than tricyclic antidepressants. A serious side effect of trazodone is priapism. This reaction is seen rarely (about 1 in 6000 male patients). It can cause considerable problems, requiring the local injection of noradrenaline agonists or even surgical treatment (Rudorfer & Potter, 1989).

6.06.7.5.4 Nefazodone

Nefazodone is related to trazodone but lacks α_1-adrenoceptor antagonist properties and is therefore less sedating. Like trazodone it has mild serotonin reuptake blocking properties, and is metabolized to the serotonin receptor agonist *m*CPP.

Controlled trials in patients with major depression have shown that in doses of 400 mg and greater, nefazodone is more effective than placebo and generally equal in therapeutic activity to comparator drugs (Rickels, Schweizer, Clary, Fox, & Weise, 1994). As with trazodone, these studies have focused on outpatients with moderate depressive disorders. Nefazodone is usually given in two divided doses starting at 200 mg daily with titration to 400 mg daily after about a week. The maximum dose is 600 mg.

Nefazodone is generally well tolerated with the most common side effects being headache, loss of energy, dizziness, dry mouth, nausea, and somnolence. It appears less cardiotoxic than tricyclic antidepressants and is less likely than SSRIs to cause insomnia and sexual dysfunction (Robinson et al., 1996).

6.06.7.5.5 Venlafaxine

Venlafaxine is a phenylethylamine derivative which produces a potent blockade of both serotonin and noradrenaline reuptake. In this respect the pharmacological properties of venlafaxine resemble those of clomipramine. However, unlike clomipramine and other tricyclic antidepressants, venlafaxine has a negligible affinity for other neurotransmitter receptor sites and so lacks sedative and anticholinergic effects. Venlafaxine is classified as a selective serotonin and noradrenaline reuptake inhibitor (SNRI). Venlafaxine has been studied in both inpatients and outpatients with major depression and compared with placebo and active comparators. Current studies suggest that it is more effective than placebo and at least of equal efficacy to other available antidepressant drugs. Venlafaxine also appears to be effective in depressed inpatients, perhaps more so than fluoxetine (Clerc, Ruimy, & Verdeau-Pailles, 1994; Feighner, 1994).

Venlafaxine has a wider dosage range than SSRIs, from 75 mg to 375 mg daily, in two divided doses. Higher doses are associated with a greater incidence of adverse effects. The usual starting dose of venlafaxine is 75 mg daily which may be sufficient for many patients. Upward titration can be considered where there is insufficient response, or if a faster onset of therapeutic activity is needed.

The adverse effect profile of venlafaxine resembles that of SSRIs, with the most common adverse effects being nausea, headache, insomnia, and sexual dysfunction. Venlafaxine occasionally causes postural hypotension but, in addition, dose-related increases in blood pressure can occur. Blood pressure monitoring may be advisable in patients receiving more than 200 mg of venlafaxine daily. Sudden discontinuation of venlafaxine has been associated with symptoms of fatigue, nausea, and dizziness. It is recommended that the dose should be reduced gradually over at least a one week period. Preliminary evidence suggests that venlafaxine is less toxic in overdose than tricyclic antidepressants (Feighner, 1994).

6.06.7.5.6 Bupropion

Bupropion is marketed for the treatment of depression in the USA but not in Europe. It is a unicyclic compound whose pharmacological properties are not well characterized. It may, however, have some activity as a dopamine and noradrenaline reuptake inhibitor (Ascher et al., 1995). Bupropion has activating properties, and early in treatment can cause restlessness and insomnia. However, it does not cause significant sexual dysfunction. Bupropion is associated with an increased risk of seizures, particularly where the dose exceeds 450 mg daily (Rudorfer & Potter, 1989).

6.06.7.5.7 L-Tryptophan

L-Tryptophan is a naturally occurring amino acid, present in the normal diet. About 500 mg of tryptophan is consumed daily in the typical Western diet. Most ingested tryptophan is used for protein synthesis and the formation of nicotinamide nucleotides; only a small proportion (about 1%) is synthesized to serotonin via 5-hydroxytryptophan. There is only weak evidence that L-tryptophan has antidepressant activity, although it may be superior to placebo in moderately depressed outpatients. There is rather better evidence that L-tryptophan combined with MAOI treatment can enhance the antidepressant effects of MAOIs. Similar synergistic effects have been reported in some studies of L-tryptophan combined with tricyclics, although overall the therapeutic effect of this combination seems inconsistent (Chalmers & Cowen, 1990).

L-Tryptophan is generally well tolerated, although nausea and drowsiness soon after dosing are not unusual. In the early 1990s, the prescription of L-tryptophan began to be associated with the development of a severe scleroderma-like illness, the eosinophilia-myalgic syndrome, in which there is a very high circulating eosinophil count (about 20% of peripheral leucocytes). Associated symptoms were severe muscle pain, edema, skin sclerosis and peripheral neuropathy. Some fatalities occurred. It is now reasonably well established that EMS is not caused by L-tryptophan itself but rather by a contaminant formed in the manufacturing process used by a particular manufacturer (Kilbourne, Philen, Kamb, & Falk, 1996). L-Tryptophan remains available for the treatment of severe refractory depression when it is used as an adjunct to other antidepressant medication. Patients receiving L-tryptophan require close supervision, including monitoring for possible symptoms of EMS and regular blood eosinophil counts. L-Tryptophan should be withdrawn if there is any evidence that EMS may be developing.

6.06.8 MOOD-STABILIZING DRUGS

Under this heading are grouped three agents, lithium, carbamazepine, and sodium valproate. These three drugs have efficacy in the prevention of recurrent mood disorders and also in the acute treatment of mania. Lithium also has useful antidepressant effects in some circumstances (Price, 1989), but the antidepressant activity of carbamazepine and sodium valproate is less well established. Lithium has also been shown to lower the frequency of aggressive behavior in patients with learning difficulties (Nilsson, 1993).

6.06.8.1 Lithium

6.06.8.1.1 Pharmacology

The mode of action of lithium is uncertain. Lithium does not affect neurotransmitters or their receptors directly, but appears to have important effects on intracellular signaling molecules, or second messengers, that are activated when a neurotransmitter or agonist binds to a specific receptor. Through these actions lithium could exert profound effects on a wide range of neurotransmitter pathways. It has been proposed that the effects of lithium may be particularly apparent when the turnover and recycling of second messengers is increased, and accordingly lithium may act preferentially to inhibit overactive neurotransmitter systems (Lithium Mechanisms Study Group 1993).

6.06.8.1.2 Efficacy

It is estimated that about 50% of patients with bipolar disorder will have a good prophylactic response to lithium. Some patients who respond well have a complete cessation of mood swings, whereas others experience markedly dimished symptomatology in which subclinical mood swings can still be discerned (Goodwin & Jamison, 1990). Lithium is also effective in the acute treatment of mania but may need to be supplemented with antipsychotic drugs if psychotic symptoms are present (Chou, 1991). About 50% of patients with a depressive syndrome unresponsive to antidepressant drugs will show a clinical response if lithium is added to their drug treatment (Price, 1989). Lithium alone has some acute antidepressant activity, most apparent in patients with an underlying bipolar disorder (Goodwin & Jamison, 1990).

6.06.8.1.3 Adverse effects

Common side effects include tremor of the hands, dry mouth, a metallic taste, feelings of muscular weakness, and fatigue (Table 10). Thirst and increased urine volume are also common. Most patients taking lithium have some minimal defect of renal tubular concentrating ability, but this rarely leads to clinical problems. A few patients, however, develop a diabetes insipidus-like syndrome with frequent passage of large volumes of water.

Weight gain during lithium treatment is quite common, and partial hair loss has sometimes been reported. Thyroid gland enlargement occurs in about 5% of patients taking lithium. Lithium also interferes with thyroid production, and hypothyroidism occurs in up to 20% of patients. Tests of thyroid function should be performed every six months to help detect these changes, but patients should also be monitored clinically for signs of hypothyroidism, particularly lethargy and substantial weight gain. If hypothyroidism develops and the reasons for lithium treatment are still strong, thyroxine treatment should be added. Lithium has rarely been associated with elevated serum calcium levels in the context of hyperparathyroidism.

Lithium is also associated with reversible ECG changes that do not seem to be of particular consequence for cardiac conduction. Other changes include an elevated white count and occasional rashes.

Most concern around the adverse effects of lithium is centred on possible long-term renal damage. As mentioned above, most patients taking lithium have some mild impairment of renal tubular concentrating ability. However, this usually recovers when the drug is stopped, although there are some reports of persisting cases. There have also been reports of tubular damage in patients taking prolonged lithium treatment.

Several follow-up studies have examined the effect of longer-term lithium maintenance treatment on glomerular function. It has been concluded that long-term lithium treatment, in the absence of toxic blood levels, does not result in a lowering of renal filtering ability (glomerular filtration rate) (Gelder et al., 1996). However, although lithium may not significantly lower the mean glomerular filtration rate in groups of patients with bipolar illness, there are case reports of increases in plasma creatinine in lithium-treated subjects when other causes of nephrotoxicity appear to be absent. Whether lithium treatment, in the absence of toxic blood levels, can cause frank renal failure is unclear (Gelder et al., 1996). With the current trends towards long-term prophylaxis of mood disorders, it is clearly wise to monitor biochemical measures of renal function regularly. It seems likely that the risk of nephrotoxicity will be minimized by avoiding toxic blood levels and maintaining plasma lithium levels at the lower end of the therapeutic range.

Effects on memory are sometimes reported by patients who complain of every-day lapses of memory, such as forgetting well-known names. Although this impairment may be associated with the mood disorder rather than lithium, there is evidence that lithium can impair certain cognitive tasks in healthy volunteers (Glue, Nutt, Cowen, & Broadbent, 1987).

Sudden discontinuation of lithium in patients with bipolar illness can result in the rapid development of mania in up to 50% of subjects. This is thought to represent a rebound phenomenon (Goodwin, 1994). Rates of relapse

Table 10 Some adverse effects of lithium and carbamazepine.

Effect	*Lithium*	*Carbamazepine*
Neurological	Tremor, weakness, dysarthria, ataxia, impaired memory, seizures (rare)	Dizziness, weakness, drowsiness, ataxia, headache, visual disturbance
Renal/fluid balance	Increased urine output with decreased urine-concentrating ability; thirst, diabetes insipidus (rare), edema	Low sodium states, edema
Gastrointestinal/hepatic	Altered taste, anorexia, nausea, vomiting, diarrhea, weight gain	Anorexia, nausea, constipation, hepatocellular damage
Endocrine	Decreased thyroxine with increase TSH,[a] goitre, hyperparathyroidism (rare)	Decreased thyroxine with normal TSH[a]
Hematological	Leucocytosis	Leucopenia, agranulocytosis (rare)
Dermatological	Acne, exacerbation of psoriasis	Rashes
Cardiovascular	ECG changes (usually clinically benign)	Cardiac conduction disturbances

[a] TSH = thyroid-stimulating hormone.

are significantly less when lithium is stopped gradually over several weeks (Baldessarini, Tondo, Floris, & Rudas, 1997).

6.06.8.1.4 *Toxic effects*

Toxic effects of lithium are related to dose. Because therapeutic blood levels (0.5–1.0 mmol/1) are close to levels at which toxicity may be experienced (> 1.5 mmol/l) it is important for both patient and clinician to be aware of symptoms of toxicity. They include ataxia, poor coordination of limb movements, muscle twitching, slurred speech, and confusion. Such symptoms constitute a serious medical emergency for they can progress through coma and fits to death. If these symptoms appear, lithium must be stopped at once and a high intake of fluid provided. In severe cases renal dialysis may be needed. There have been reports of permanent neurological damage in patients who have suffered from lithium toxicity. It is important to note that certain commonly used medical drugs, such as thiazide diuretics and nonsteroidal antiinflammatory drugs, can elevate lithium levels and cause toxic effects (Gelder et al., 1996).

6.06.8.1.5 *Lithium and pregnancy*

Lithium crosses the placenta, and retrospective studies have found increased rates of abnormalities in the babies of mothers receiving lithium in pregnancy. For example, a rate of 7% has been reported, with most abnormalities affecting the baby's heart. However, a prospective study of 148 women found no increase in congenital malformation in patients exposed to lithium in the first trimester of pregnancy compared with matched controls. These authors concluded that lithium did not appear to be an important human teratogen (Jacobson et al., 1992). However, this conclusion was based on relatively few patients.

Clearly, it is desirable for patients to be medication-free during the first trimester of pregnancy, and the decision whether or not to continue with lithium treatment must be carefully weighed. Important factors include the likelihood of affective relapse if lithium is withheld. If pregnant patients continue with lithium, plasma levels should be monitored closely. Ultrasound examination and fetal echocardiography are valuable screening tests as the pregnancy progresses.

Patients with a history of bipolar disorder have a substantially increased risk of psychotic relapse in the postpartum period. In such patients it may be worth considering the introduction of lithium shortly after delivery to provide a prophylactic effect. However, it should be noted that lithium is secreted into breast milk and that significant concentrations of lithium can be measured in the plasma of breast-fed infants.

6.06.8.2 Carbamazepine

Carbamazepine was originally introduced as an anticonvulsant and was found to have useful effects on mood in certain patients. Subsequently it was found to be beneficial in many bipolar patients, including those who had proved refractory to lithium. The acute antidepressant effect of carbamazepine is not established (Post, 1991).

6.06.8.2.1 Pharmacology

Like certain other anticonvulsants, carbamazepine blocks neuronal sodium channels. It is unclear whether this action plays a role in its mood-stabilizing effects. Like lithium, carbamazepine facilitates some aspects of brain serotonin function.

6.06.8.2.2 Efficacy

In the treatment of acute mania, carbamazepine is of about equal efficay to lithium. In the prophylaxis of bipolar illness, carbamazepine is also about as effective as lithium, although the quality of the trials has been criticized (Dardennes, Even, Bange, & Heim, 1995). Based on a survey of controlled and uncontrolled trials (Post, Denicoff, Frye, & Leverich, 1997) it is estimated that about 65% of patients with bipolar illness show a clinically significant prophylactic response to carbamazepine either given alone or added to lithium. However, there is some evidence that in some patients an initial response can diminish with time suggesting that tolerance to the mood-stabilizing effects of lithium can occur (Post, Leverich, Rosoff, & Altschuler, 1990).

6.06.8.2.3 Adverse effects

Adverse effects with carbamazepine are common at the beginning of treatment (Table 10). They include drowsiness, dizziness, ataxia, diplopia, and nausea. Tolerance to these effects usually develops quickly. A potentially serious side effect of carbamazepine is agranulocytosis, although this complication is very rare (variously estimated from 1 in 10 000 to 1 in 125 000 patients). A relative leucopenia is more common, with the white cell count falling in the first few weeks of treatment, though usually remaining within normal levels. Rashes occur in about 5% of patients. Elevations in liver enzymes may occur and, rarely, hepatitis has been reported. Carbamazepine can also cause significant disturbances of cardiac conduction, and therefore is contraindicated in patients with preexisting abnormalities of cardiac rhythm. Carbamazepine has also been associated with low sodium states.

The use of carbamazepine in pregnancy has been associated with neural tube defects in the fetus. The risk is diminished by adequate folate intake.

6.06.8.3 Sodium Valproate

Like carbamazepine, sodium valproate was first introduced as an anticonvulsant. In recent years there has been increasing interest in using the drug in the management of mood disorders, particularly acute mania and the prophylaxis of bipolar disorder in patients unresponsive to lithium and carbamazepine. There is presently little evidence that valproate has acute antidepressant effects (McElroy, Kerk, & Pope, 1987; Post, 1991).

6.06.8.3.1 Pharmacology

Valproate is a simple branch-chain fatty acid with a mode of action that is unclear. However, there is some evidence that it can slow the breakdown of the inhibitory neurotransmitter GABA. This action could account for the anticonvulsant properties of valproate, but whether it also underlies the psychotropic effects is unclear.

6.06.8.3.2 Efficacy

There have been several controlled studies suggesting that valproate is effective in the acute management of mania, but there are no controlled investigations of its efficacy in the prophylaxis of bipolar disorder (McElroy, Kerk, Pope, & Hudson, 1992). There have, however, been numerous case series and open studies that have reported useful prophylactic effects of valproate in patients unresponsive to lithium and carbamazepine, including those with rapid cycling mood disorders (McElroy et al., 1987, 1992; Post, 1991).

6.06.8.3.3 Adverse effects

Common side effects of valproate include gastrointestinal disturbances, tremor, sedation, and tiredness. Other troublesome side effects include weight gain and transient hair loss with changes in texture on regrowth. Patients taking valproate may have some elevation in hepatic transaminase enzymes; provided this increase is not associated with hepatic dysfunction the drug can be continued while enzyme levels and liver function are carefully monitored. However, there have been several reports of fatal hepatic toxicity associated with valproate; thus far these reports have been confined to children taking multiple anticonvulsant drugs. Valproate must be withdrawn immediately if vomiting, anorexia, jaundice or sudden drowsiness occur. Valproate may also cause thrombocytopenia and may inhibit platelet aggregation. Acute pancreatitis is another rare but serious side effect, and increases in plasma ammonia have been reported. Other possible side effects include edema, amenorrhoea and rashes. The use of valproate in pregnancy has been associated with neural tube defects and bleeding in the neonate.

6.06.9 CLINICAL USE OF PSYCHOTROPIC DRUGS

6.06.9.1 Anxiety Disorders

6.06.9.1.1 Generalized anxiety disorder

In generalized anxiety disorder (GAD) drugs are generally used as an adjunct to psychological methods of treatment (Table 11). Benzodiazepines are now prescribed only for short-term use (2–4 weeks) in patients where anxiety is causing severe distress and functional impairment. Benzodiazepines have a number of advantages as short-term treatment in that they are rapidly effective and have a wide safety margin. It is usually best to give benzodiazepine treatment on an as-required basis in doses of 2.5–5 mg. Intermittent use of this nature is less likely to result in tolerance (Tyrer, 1997).

Tricyclic antidepressant drugs and trazodone have also been shown to be effective in GAD in the same doses that are effective in treating major depression (Rickels et al., 1993). SSRIs have not been formally tested in this disorder but clinical impression suggests that they are likely to be useful. The azapirone buspirone is also effective in GAD, particularly in patients who have not received significant prior benzodiazepine treatment. All these treatments take longer to work than benzodiazepines. Their ultimate effect over 6–8 weeks, however, is at least as great (Cowen, 1997).

Where psychological treatments have not helped or are not available, buspirone or antidepressant drugs rather than benzodiazepines should now be used for longer-term treatment of GAD. The choice will lie between a sedating compound, such as a tricyclic antidepressant, or nonsedating treatments such as buspirone or an SSRI. Although, sedation has some advantages for patients with sleep disturbance and agitation, in the longer-term, buspirone or SSRIs are likely to be as effective and have less risk of cognitive impairment. There is little information about the combined use of medication and psychological treatment in GAD. There has been concern, however, that the cognitive impairment produced by benzodiazepines may decrease the ability of the patient to carry out psychological treatments.

6.06.9.1.2 Panic disorder and agoraphobia

A number of drug treatments are effective in panic disorder. These include high potency benzodiazepines such as alprazolam and clonazepam, as well as tricyclic antidepressants such as imipramine and clomipramine (Lydiard & Ballenger, 1987; Modigh, Westberg, & Eriksson, 1992). SSRIs are also effective and paroxetine is licensed for the treatment of panic disorder in the UK (Oehrberg et al., 1995). MAOIs are good antipanic drugs but are little used because of their adverse food and drug interactions (Nutt & Bell, 1997; Nutt & Glue, 1989).

Overall, all these drugs have efficacy in both preventing panic attacks and lessening phobic avoidance. However, antidepressants are difficult to use in panic disorder because initial treatment often produces symptomatic worsening and jitteriness. For this reason a low starting dose and careful titration are required. However, to obtain the best clinical response it is necessary eventually to build the doses up so that they are similar to those required in major depression (Mavissakalian & Perel, 1995). The

Table 11 Spectrum of activity for anxiolytic drugs.

Drug	*Generalized anxiety disorder*[a]	*Panic disorder*[b]	*Social phobia*	*Obsessive-compulsive disorder*
Benzodiazepines	+	+[c]	?[c]	0
Buspirone	+	–	?	0
TCAs	+	+	–	0[d]
SSRIs	?	+	+	+
MAOIs	?	+	+	0

[a] + = effective; – = not effective, ? = uncertain. [b] With or without agoraphobia. [c] High potency compound (alprazolam, clonazepam). [d] Clomipramine effective.

high potency benzodiazepines, alprazolam, and clonazepam, have the advantage of not causing increased anxiety early in treatment and this makes them easier to use (Schweizer, Rickels, Weiss, & Zavodnick, 1993). However, withdrawal of these drugs in patients with panic disorder can be very difficult (Fyer et al., 1987).

Cognitive behavior therapy is effective in panic disorder and has the advantage that relapse is less common after the end of treatment than it is after drug treatment is withdrawn (Clark et al., 1994). Antidepressant treatment retains a useful place in patients who are not able to benefit from cognitive therapy. It is posssible that the combination of behavior therapy and antidepressant treatment might produce increased efficacy (de Beurs, Vanbalkom, Lange, Koele, & Van Dyke, 1995). A small potentiation of treatment efficacy was also apparent when alprazolam was added to exposure therapy for patients agarophobia and panic. However, alprazolam-treated patients showed less improvement after the end of the study (Marks et al., 1993). Alprazolam also produced significant impairments on word recall tasks (Curran et al., 1994).

6.06.9.1.3 Obsessive-compulsive disorder

Drugs that produce marked potentiation of brain serotonin function, such as SSRIs and clomipramine, are effective in obsessive-compulsive disorder (OCD). About 50% of patients are much improved, although recovery is rarely complete. Similar doses or somewhat higher are used in the treatment of OCD as in major depression. Both obsessional ruminations as well as rituals respond to drug treatment. The time course of response is rather longer than in major depression with a linear rate of improvement beginning at about 4 weeks and continuing for 12 weeks and more (Jenike, 1992).

There is little evidence that drug treatment increases the effect of behavior therapy in patients able to comply with this treatment (Cobb, 1992). However, drug treatment has a role in patients who cannot undertake behavior therapy or who are unresponsive to it. Relapse rates are much less after successful behavior therapy than after withdrawal of antidepressant drug treatment. It has therefore been suggested that, where patients have improved with drug treatment, behavior therapy may be added with the aim of facilitating drug discontinuation (Cobb, 1992).

6.06.9.1.4 Social phobia

There is less evidence about the utility of drug treatment in the management of social phobia, although there is evidence from controlled trials that treatment with SSRIs and MAOIs may confer benefit (van Vliet, den Boer, & Westenberg, 1994; Versioni, Nardi, & Mundim, 1992). Interactions of drug treatment with psychological treatment have not been systematically studied.

6.06.9.2 Insomnia

Insomnia is a common health problem in community samples (Lasagna, 1995). Although hypnotic drugs such as temazepam and zopiclone are effective in the short term, continued use may result in tolerance and rebound insomnia often occurs upon drug discontinuation. It is recommended therefore that hypnotic drugs be employed only for short-term treatment. Many people with insomnia use other pharmacological remedies such as sedating antihistamines or alcohol (Lasagna, 1995). These measures are generally of limited utility. The role of the pineal hormone melatonin is arousing increasing interest but controlled longitudinal studies are rare (Gafinkel, Laudon, Nof, & Zisapel, 1995).

There are a number of psychological methods of helping insomnia (Morin, Culbert, & Schwartz, 1994). These should be preferred to drug treatment in the first instance because they have fewer adverse effects and their benefits, if obtained, are likely to persist for longer.

6.06.9.3 Depression

Antidepressant drugs are used in the treatment of major depression and dysthymia (Depression Guideline Panel, 1993). Antidepressant drugs appear to be of definite value in more clinically severe depressions, particularly those that meet criteria for melancholic features (*DSM-IV*) or somatic symptoms (*ICD-10*) (Depression Guideline Panel, 1993). Although some improvement in depressive symptoms may be seen in the first week of treatment, generally antidepressant drugs can take 4–6 weeks to exert clinically important effects (Depression Guideline Panel, 1993; Quitkin et al., 1996).

6.06.9.3.1 Choice of antidepressant

As noted above several kinds of antidepressant treatment are available which are of generally equivalent efficacy in the broad range of depressed patients. For the more severely depressed subjects, however, treatment with a tertiary tricyclic antidepressant, such as amitriptyline or clomipramine or the SNRI venlafaxine, should be considered (Anderson, 1997).

For other patients the choice can be made according to the symptom profile of the antidepressant and the needs of the patient. For example, in subjects striving to carry on with their usual work and social activities, relatively nonsedating compounds such as lofepramine, nefazodone, SSRIs or venlafaxine would be suitable. Tertiary tricyclics may be helpful when sleep disturbance is severe or when rapid sedation is needed. In some patients, however, tricyclic antidepressants will be contraindicated because of their anticholinergic and cardiovascular side effects. Sedating compounds suitable in this situation include trazodone and mirtazepine. With the exception of lofepramine, tricyclic antidepressants should not be prescribed where there is a risk of deliberate overdose. MAOIs will generally be used as second- or third-line drugs because of their food and drug interactions.

6.06.9.3.2 Prophylaxis of recurrent major depression

Once a patient has responded to antidepressant drug therapy, drug treatment is usually continued for at least 6 months to prevent relapse of syptoms; this is called continuation therapy (NIMH Consensus Development Conference Statement, 1985). In patients with recurrent major depression longer-term prophylactic drug therapy is often required to prevent frequent disabling recurrences. Generally, if an antidepressant is effective in acute phase treatment, it will provide a useful prophylactic effect during long-term treatment (Quitkin et al., 1996). However, some patients respond better to lithium prophylaxis or to the combination of antidepressant and lithium.

6.06.9.3.3 Psychological therapies and antidepressant drug treatment

Specific psychotherapies such as interpersonal therapy (IPT) and cognitive behavior therapy are effective in the treatment of major depression. In general, patients with more severe depression appear to do less well with psychotherapy. For example, both IPT and cognitive behavior therapy appear less effective in patients with disturbances of sleep architecture (Thase et al., 1997; Thase, Simons, & Reynolds, 1996), a common feature of depression with melancholic features. It has also been reported that patients who fail respond to cognitive therapy can subsequently show benefit with antidepressant medication (Stewart, Mercier, Agosti, Guardino, & Quitkin, 1993).

There is a strong clinical impression that combinations of psychotherapy and antidepressant medication may be more efficacious than either alone in patients whose depression is complicated by interpersonal and social difficulties, but few controlled trials exist to sustain this opinion (Depression Guideline Panel, 1993).

There have been studies of drug and psychotherapy interactions in the longer-term treatment of depression. For example, Frank et al. (1990) found that interpersonal therapy given once monthly delayed, but did not prevent, depressive recurrence compared to placebo medication and clinical management. In the same study interpersonal therapy did not augment the effect of impiramine to prevent depressive recurrence. There is some evidence that cognitive therapy can decrease the risk of subsequent relapse (Blackburn, Eunson, & Bishop, 1986). If this is the case it could be a very useful treatment for the many patients who wish to discontinue medication but are unable to do so because of symptomatic recurrence.

6.06.9.4 Mania

Mania is generally treated with mood-stabilizing drugs and antipsychotic medication. In the USA antipsychotic drugs are avoided as far as possible because of the risk of movement disorders and treatment with lithium or valproate preferred (Chou, 1991). It is important to note that the plasma level of lithium effective in mania (0.8–1.2 mmol/l) is somewhat higher than the range recommended for prophylaxis (0.5–0.8 mmol/l) (Prien, Caffey, & Glett, 1992).

In the UK, because of the risk of lithium rebound upon sudden disontinuation (Goodwin, 1994), antipsychotic medication tends to be used more in the treatment of acute mania. In general, conventional antipsychotic drugs such as chlopromazine and haloperidol are employed; there is little information on the efficacy of newer antipsychotic drugs such as risperidone and olanzepine. Benzodiazepines may be employed for sedation (Chou, 1991). The treatment of mania requires skilled nursing and psychological management but specific interpersonal or cognitive therapies are not generally used.

6.06.9.5 Prophylaxis of Bipolar Illness

Bipolar illness is a recurrent disorder and prophylaxis with mood-stabilizing drugs is a mainstay of treatment. A major problem in the management of bipolar disorder is lack of compliance with treatment. This has a variety of causes, ranging from adverse effects of drugs to the difficulty that people experience in coming to terms with life-long serious illness which requires continued drug treatment. In addition, patients need to learn to recognize minor mood changes that may be the prodrome for more serious mood disturbances unless action is taken. It is possible to address these issues in a number of ways, ranging from education to formal cognitive behaviour therapy. Such measures improve the prognosis in bipolar disorder (Jamison, 1994).

6.06.9.6 Schizophrenia

Antipsychotic drugs are necessary for the acute treatment of psychosis and are also required for long-term prophylaxis in many patients. First-line drug treatment has usually been with chlorpromazine or haloperidol. However, such drugs are likely to be gradually replaced with newer atypical agents such as risperidone and olanzepine because of the decreased incidence of movement disorders and somewhat greater efficacy of the latter agents (Marder & Meibach, 1994; Tollefson & Sanger, 1997).

Atypical agents are not available yet in parenteral form and, where oral medication is not possible, intramuscular administration of conventional antipsychotic drugs has to be employed. As noted above, current trends are to use low doses of a high potency agent such as haloperidol with additional benzodiazepine medication if required (Pilowsky et al., 1992).

For longer-term prophylactic treatment, again atypical agents may be preferred. If depot preparations are needed, however, conventional drugs such as flupenthixol, fluphenazine or haloperidol have to be used.

Most patients with schizophrenia continue to experience a level of positive and negative symptoms despite drug treatment. There is growing interest in the use of cognitive behavior therapy in addition to medication in schizophrenia. There is evidence that combined drug and psychotherapy in selected patients can improve the resolution of delusions and hallucinations (Drury, Birchwood, Cochrane, & Macmillan, 1996).

As with the long-term management of bipolar illness, lack of compliance with medication is a major problem in patients with schizophrenia. There is evidence that cognitive therapy designed to help the patient evaluate their attitudes to their illness and its treatment may improve the take up of drug therapy (Kemp, Hayward, Applewhaite, Everitt, & David, 1996).

6.07.1 INTRODUCTION

The theoretical development of psychotherapy has not been smooth; theories have evolved largely through conflict and revolution rather than through an orderly progression of evidence and discovery. From the beginning, Freud demanded unswerving loyalty to his viewpoints, an unrealistic expectation given that the topic of discourse was, at that time, so poorly understood, and that the concepts were so complex and subjective. Freud's lack of sympathy toward those whose perspectives came to diverge from his own extended to a point that even minor disagreements with former disciples resulted frequently in the development of different "schools"; old allegiances and friendships were lost, and theoretical constructs became rigidly reified by the vigorous defenses erected against annihilation by their proponents. This history of dispute and division left a legacy of fragmentation in psychotherapy theory; hundreds of schools of thought have evolved with the very nature of evidence being in hot dispute. As clients and prospective clients, as well as practitioners and scientists, this is the legacy that remains (Bergin & Garfield, 1994; Freedheim, 1992).

In order to both capture the breadth of the field and to bring some order to it, it is useful to conceptualize the field as being composed of various overlapping levels of specificity. At least three such levels, systems, models, and theories, are necessary to capture the color and diversity of the field of psychotherapy.

Most theorists generally identify psychotherapy as evolving from three major systems or schools (Rice & Greenberg, 1992). Each of these intellectual systems continue in somewhat modified form from their initial beginnings and in contemporary psychotherapy, are composed of models and theories, all of which share a common but distinctive view of what motivates behavior. The first system in this evolution is the collection of viewpoints that are often referred to as "psychoanalytic" or "psychodynamic." This system is distinguished from the other two by its reliance on the concept of intrapsychic conflict as the basis of motivation and change. It arose with the ideas of Freud in the first two decades of the twentieth century, and expanded through the contributions both of Freud's (former) disciples and from the application of his ideas to the theories that are known as ego-psychology, self-psychology, and object relations.

The second system in the evolution of psychotherapy came to prominence in the 1940s and 1950s. The behavioral school replaced the concept of intrapsychic conflict with "Reinforcement" as the basic motivating force of behavior. Conditioning, along with its variants of learning by association and consequences, became the primary explanatory construct.

Experiential schools, the "third force" in psychotherapy (Rice & Greenberg, 1992), in contrast to the first two, view motivation as an inherent struggle for integration and growth. Thus, rather than being either driven by base instincts, that were inherently destructive and negative, or by external consequences, that were inherently neutral in social value, self-actualization assumed a decidedly positive valence, moving the individual toward increasingly social and enhancing ends.

Within each of these three systems there are a variety of more specific models that describe how the general system or movement is translated to the specific example of psychotherapy. Each of these models share the view of the larger group, the school, regarding the basis of motivation, but differ in how they think these motives are manifest in psychopathology and how they are addressed in psychotherapy. Specifically, for example, within the larger movement of "Psychoanalytic Theory," as has already been mentioned, there are models based on ego-psychology, self-psychology, and objects-relations theory. "Experiential Theory," likewise, is comprised of existential, humanistic, and person-centered models of psychotherapy; within the behavioral school are radical behaviorism, social learning theory, and cognitive models. Each of these models poses a slightly different view of how behavior is best changed and what aspects and patterns of motives are likely to be manifest in this process.

A third and more specific ordering of theory identifies specific theories of psychotherapy. These theories typically are identified by certain strategies and techniques that distinguish them from others, even within the same model and system. Beck's theory of cognitive therapy is different from that of Ellis, for example, though they both are representative of a cognitive model of psychotherapy.

Again, using the example of Experiential Theory, within the model of existentialism, Daseinsanalysis and Logotherapy represent different, specific, theoretical contributions; within the humanistic tradition, Gestalt Therapy and Redecision Therapy may be recognizable and distinct, and within a phenomenological model, client-centered and person-centered therapies represent a line of evolution within a single theory.

It bears mentioning that some believe that two other systems or schools are sufficiently distinct from their roots and are vying for status as major, independent "forces" in psychotherapy. Cognitive models of behavior are certainly strong contenders for this status. Given that they pose the same motivational system that characterizes behavioral theories, however, it is unlikely that they qualify as a distinctive, major system of the order of psychoanalytic, behavioral, and experiential theories. Similarly, while integrative models are widespread and influential, it is difficult to find a characteristic, common, and distinguishing set of theoretical assumptions. These issues will likely prevent both cognitive and integrative models of intervention from being elevated to the level of a "fourth force" in psychotherapy.

The very presence of these emerging and competing systems, however, and the many variations of theory that they represent, testify to the fragmentation of the field. Certainly, the diversity of psychotherapeutic approaches is substantially greater than might be judged if the view were only at the level of the three broad systems to which theorists often refer. Though it seems that no one has taken the time to count them, there are clearly more than 400 specific theories and an indefinite number of intermediate level models representing these.

6.07.1.1 The Diversity of Experiential Therapies

"Experiential Therapy" is a broad designation within which there is a rich array of diversity. Humanistic, existential, and phenomenological models are well accepted as being subdivisions of this general system. The identity of the more specific theories that represent these models, however, is less consistent. Some theories are not easily classified within a single model while others are blends of two or more. Thus, some authors identify constructivist approaches such as that of Kelly (1955) as an experiential theory (e.g., Bugental & McBeath, 1995; Feshbach, Weiner, & Bohart, 1996), while others identify it as a variant of behavioral or psychodynamic schools (e.g., Mahoney, 1993). The basis of this disparity is not obvious. While this variability suggests that there is a lack of reliability in assigning at least some theories of psychotherapy to general models or schools, it also illustrates the cross-theory blending that is a part of the experiential movement itself.

Culturally, experiential philosophies are ingrained deeply in the values of hard work and sacrifice, the values of the industrial and Protestant revolutions. The evolution of these theories was forever colored by the experiences of holocaust survivors and others who suffered the ravages of war and prolonged catastrophe (e.g., Frankl, 1961). While their theoretical roots date to the European philosophers of the eighteenth and nineteenth centuries, as a domain of practice and service, experiential therapies are largely a post-WWII development. They represent the "transplanting of existential thinking from their chiefly European intellectual roots to a broader US audience of nonmedical, unphilosophically sophisticated, practicing counselors and therapists" (Bugental & McBeath, 1995, p. 112).

Rice and Greenberg (1992; modified from Tageson, 1982) point out that the various theoretical variations within experiential theory share: (i) a reliance on phenomenology as a method of study, (ii) an assumption that in-born actualizing tendencies motivate behavioral development and change, and (iii) a belief in individual choice as the causal locus of behavior.

6.07.1.1.1 Experiential theory as a method of study

The methods that are used by experiential psychotherapists are phenomenological and individualistic, contrasting with the objective, external, and pluralistic methods of psychoanalytic and behavioral models. It is assumed that healing of the most complex problem will occur naturally by acquiring a deep understanding of each individual's unique personal experience of the world in which they live. An assessment of either the truth or value of this personal experience is not reliant on external criteria, but on the person's own subjective standard, their capacity to assess that standard through a process of reflective awareness, and the degree to which the resulting understanding furthers the self-actualization of the individual. Knowledge, as defined through the conventional scientific standards of empirical observation and externally measured but collective responses, is thought to be inadequate unless it deepens an understanding of the unique phenomenology of the person.

The assumption that "Truth" is in the patient's experience contrasts both with psychoanalytic and behavioral views. These latter views identify the therapist, rather than an external body, as the nucleus of knowledge. In psychoanalysis, for example, insight and knowledge come from the therapist's or analyst's interpretation, not from the patient, through the mechanism of interpretation. Thus, it is the analyst, not the analysand, who defines the veracity and validity of experience. Likewise, in behavioral models, the therapist is considered to be the expert or authority whose critical understanding of behavior serves as the guide for developing a technical correction. From the therapist, not the patient, come the suggestions and guidance that are then further supported by homework assignments from the therapist. In both of these views, the value of evidence is proportional to the degree to which the therapist-observer can remain objectively distant from the observed, the patient.

In contrast, in existential/humanistic analysis, information flows from patient to therapist, rather than vice versa. The veracity of an experience is defined, for the experiential-humanist, by self-reflection and personal authenticity. The process of exploring and identifying the nature and content of self-appraisal is not controlled by the therapist; it is only facilitated and allowed to expand by a permissive clinician. It is this self-initiated growth that is the basis of healing.

6.07.1.1.2 Experiential theory as a set of assumptions

Beutler, Bongar, and Shurkin (in press) emphasize that three assumptions both distinguish experiential therapy from psychoanalytic and behavior therapy and represent the bases that bind the specific theories within the domain of experiential models together. These binding assumptions include the beliefs that: (i) there is an innate process that directs emotional growth;

(ii) constraining this inborn tendency from its normal process of unfolding produces distress and psychopathology; and (iii) removal of these constraints in a permissive environment releases the healing process. Among the various models and theories that constitute the experiential school, however, the priority and nature of these beliefs change.

Within the mainstream of the tradition, self-actualization is the fundamental motivational force. It is an innate process that moves the organism to become increasingly complex, balanced, and integrated. Thus, self-actualization requires emotional and sensory as well as cognitive input. Sensory and emotional experiences are thought to be necessary in order to insure the adaptive incorporation of new cognitive information. As a person adapts, accommodates, and incorporates new information, they naturally become more differentiated and complex, both intellectually and interpersonally. Cognition becomes differentiated, emotions become more varied, and behavior is increasingly discriminating.

Put in this way, self-actualization is not tied to a particular set of social values. However, some theories within the phenomenology and humanistic traditions extend the definition to include the view that this growth process includes a movement toward greater productivity, self-sufficiency, creativity, and social adaptability. These definitions add a dimension of social "goodness" and tie the theory more closely to democratic social systems.

The assumption that self-actualization is an inherent drive, drawing one toward growth and differentiation is probably less easily accepted by existential theorists than it is by humanistic and phenomenological theorists (Rice & Greenberg, 1992). In existential models, self-actualization assumes a teleological definition in which growth derives from a pull from individualized goals and aspirations rather than from a force that pushes one toward more abstract, societal goals.

The second assumption underlying experiential models identifies the basis for psychopathology. This assumption points to social and familial constraint and restriction of emotional experience as a pathological force that constrains the natural process of growth and differentiation. Beutler et al. (in press) observe that most Western societies seek to restrain intense emotions and discourage the development and expression of emotions. Experiential theorists argue that this social constraint separates an individual from some of the experience that is necessary for effective information processing. This emotional constraint is based on three beliefs that are considered by experiential theorists to be fallacious and mistaken: (i) cognitive knowledge can be separated from its emotional concomitants, (ii) destructive acts are the products of intense emotions, and (iii) constraint of emotions will protect the society from these destructive acts.

Experiential theories assert that the very act of trying to protect a society by restricting the emotional experiences of its citizens has the paradoxical effect of increasing, rather than reducing, the likelihood of social discord and violence. In this view, human problems are caused, not by excessive expression, but by restraining and fragmenting the normal and necessary acts of thinking, feeling, sensing, and intuiting. Emotional constraint during the course of emotional development, in other words, prevents incorporation of the very information that promotes integration and emotional growth.

Thus, rather than reducing the likelihood of destructive acts, the efforts of society and families to protect themselves from strong emotions is thought to interrupt and fragment the experiences that allow people to develop social conscience and constraint. By becoming separated from their feelings, individuals may then engage in destructive behavior without feeling and sensing the consequences of these experiences. Both the benign failure to actualize and grow from new experience and the malignant social destructiveness of impulsive behavior, therefore, are products of these misdirected societal efforts.

The third assumption that characterizes the experiential movement identifies the basis of correcting the pathological effects of emotional constraint. This assumption defines the nature and objectives of psychotherapy. It assumes that self-actualizing tendencies and powers that have been aborted and fragmented can be reactivated in a therapeutic environment that is characterized by unconventional acceptance of emotional experience. Such an environment is thought to unencumber, allow, and encourage the reconnection of emotions and their expression. Behaviors become reattached to their emotional and sensory concomitants and consequences. By reconnecting these components of experience, self-actualization motives are reactivated, and the normal processes of growing is allowed to continue.

Experiential therapies provide an environment that is free from those arbitrary constraints that are imposed against emotion and sensing by society and by families. The psychotherapist endeavors to focus on, facilitate, sometimes even to create experiences that will magnify emotional and sensory reactions so that it can penetrate defenses that have been deadened by societal rules. The idea that human emotional needs and drives are sources of prosocial and proindividual behavior stands in contrast both with the negative nature of humankind espoused by the id psychology of psychoanalysis and with the *tabula rasa* view of personal development that characterizes most modern reinforcement psychologies.

6.07.1.1.3 Experiential theories view the source of behavior

Experiential philosophies view individuals as having ultimate control in their own lives. They are thought to be active, not only in selecting their own behavior, but in constructing their own realities. It is out of this human capacity to make their own meanings of experience that people construct goals and aspirations. It is also on these meanings that people rely when faced with oppression, physical restriction, and intellectual constraint in order to survive even the most atrocious of events.

The internal construction of meaning and worth, in these eventualities, provides armor against external, destructive forces. Self-determinism, in other words, is the prevailing principle of the experiential movement, and applies as much to thoughts and feelings as it does to behaviors.

Experiential models attempt to counter the victim-based mentality that characterizes both psychoanalytic and behavioral positions. These latter systems assign people to a position of being reactive either to instinctive urges, social disruption, or reinforcements. Unlike these alternative systems, experiential models assume that people have a proactive posture. They retain personal choice over their own perceptions and meanings. This choice is optimized when using and integrating information from the full range of sensory, perceptual, and cognitive experience. Both psychoanalytic and behavioral models are viewed as excluding sensory and emotional experience and of exaggerating the significance of societal standards, insight, and behavior.

6.07.1.2 Chapter Overview

In the rest of this chapter, attention will turn to a variety of specific psychotherapy theories that represent three models of behavior within the experiential tradition: existential, phenomenological, and humanistic psychotherapies. The discussion will be restricted largely to post-WWII developments. Using representative approaches of each of the models that comprise the experiential school as examples, theories will be traced from their post-WWII roots to their status in the 1990s.

The theoretical approaches that have been chosen to be representative of the development of the experiential system include the person-centered (or "client-centered") therapy of Carl Rogers as an example of phenomenological models; the Gestalt therapy of Fritz Perls as a representative example of humanistic models; and the Logotherapy of Victor Frankl as an example of existential models. These early theories will be traced through an evolution that has produced a large array of contemporary modifications, variations, and approaches. An exhaustive description of the offspring and research associated with the theories developed by Rogers, Perls, and Frankl is not possible within the framework of this chapter, but some representative descriptions of the progeny of each will be provided. The contemporary Gestalt therapies of Greenberg and Daldrup and their colleagues will be described; the contemporary experiential therapies of Gendlin and Mahrer and the contemporary existential therapies of May, Maslow, and Bugental.

Following a description of the historical roots of the three general theories, a more general perspective of the experiential system will describe developments in theory and practice, with a review of the research.

6.07.2 HISTORICAL DEVELOPMENT

6.07.2.1 Existential Models: The Rise of Logotherapy

Existential philosophy was transported to the field of psychotherapy from Europe via the immigration of victims of the holocaust following WWII. This philosophy found voice in the US through Frankl's (1963) *Man's search for meaning*, a treatise on survival in the concentration camps. Existential conceptualization of the individual sought to qualify and validate the experience of immediate existence, independent of the theoretical projections about human psychological functioning that were implicated historically by other theories of psychotherapy.

Frankl observed that interpersonal alienation, related either to economic status or political posturing, in conjunction with the precarious stability of social (family) structures, had the capacity to invoke debilitative anxiety. Under a war-time period of constant life-threat, existentialism congealed as a response that restored the dignity of human life and resurrected the human spirit. Theories that explain motivation by reference to homeostasis alone were incapable of capturing the complexity of the human struggle. To Frankl, therefore, it was the act of striving for meaning that formed the basis of motivation and the impetus for change.

Frankl was born in 1905 in Vienna, the seat of Freud's psychoanalysis. He founded the Youth Advisement Centers in 1928, in response to a long-standing interest in emotional well-being, shortly before completing the work for his M.D. degree (1930). As a psychiatrist and neurologist, he joined the faculty of the Department of Neurology at the Rothschild Hospital in Vienna in 1936 and rose to Department Head by 1942. He published papers in prominent journals on the topic of psychiatric and neurological treatment of neurosis, beginning in 1939, and became quite prominent in Vienna psychiatric circles even before Hitler's 1939 invasion of Poland (Patterson & Watkins, 1996).

Frankl was interned both in Auschwitz and Dachau between the years of 1942 and 1945, where he lost virtually all of his family to the gas chambers. *Man's search for meaning*, which reported his experiences there, was published in Vienna shortly after the end of the war. Subsequently he lectured widely in North America, capturing the imagination both of postwar Europe and of the American public. In spite of his great influence on American psychotherapy, Frankl never immigrated to the United States. Following the war, he assumed a full-time faculty position at the University of Vienna where he rose to the rank of Professor in 1955.

Frankl's experiences in Auschwitz and Dachau, and his intimate relationships with despair, hopelessness, depression, and imminent death, qualify him as an effective authority on suffrage and the human condition. Frankl found himself stripped to his naked existence by the atrocities of the Nazis; his father, mother, brother, and even his wife had been sent to the gas ovens. With the exception of his sister, Frankl lost his entire family to the Nazis. He faced the question of how a person who had lost virtually every possession, had every value destroyed, who was hungry and suffering with the constant thought of imminent extermination, could find life worth preserving.

Responsibility and meaning are the hallmarks of Frankl's theoretical construct of "being." These concepts speak directly to the condition of the human sufferer who has made the concession that they have nothing to lose except life, and that life itself is irrelevant without value and choice. Reflecting on his own senseless suffering and misery, Frankl concluded that to live is to suffer, and to survive is to find meaning in the suffering. Frankl believed that each individual was responsible for finding a purpose in life and that each must accept the responsibility that is prescribed by this meaning. Thus, Frankl believed, with Nietzsche, that he who has a "why" to live can bear with almost any "how."

"Being" to Frankl was trivariate, comprising spirituality, freedom, and responsibility. Spiritual awareness was cardinal in the process of being, taking precedence over freedom and responsibility, what he called the "psychophysicum." To reflect on one's self, to project meaning on experience, and to relate with forces that were bigger than one's self were the products of spiritual awareness. Freedom was second only to spirituality in the course of being. Freedom was defined as the capacity to rise above instincts, to reject or accept experience, and to do or not to do. Thus, a person had the freedom to pursue the objectives set by spiritual awareness, and this freedom represented a cardinal distinction between people and other animals. Yet the motivation to achieve meaning through spiritual consciousness and freedom were not driving but pulling forces. That is, to Frankl, freedom and striving for meaning were achieved because they drew people to action, not because it caused or compelled them to act.

In his own struggle, Frankl was forced to deal with the conspiracy of the Nazis to force the oppressed to give up on life as they saw all of their familiar benchmarks, attachments, and goals ripped away. He discovered that when life is thus controlled, and external objects and relationships are lost, some basic "human freedoms" remain; the God-given ability to choose the meanings that one assigns to experience and to choose the attitude one holds in and about the extant conditions and circumstances. It is this ultimate freedom to choose attitudes that both informed Frankl's experiences in the camps of Auschwitz and Dachau and that continue to have the capacity to guide modern people's resolution of the existential dilemma.

The third factor in Frankl's conception of being was responsibility. He came to believe that spiritual awareness and choice were matters of responsibility. One is responsible both to find meaning in one's life and to act on that meaning. Logotherapy (Frankl, 1961), therefore, placed much emphasis on helping people assess the implied responsibilities associated with the meanings they gave to their lives, and to act on their own behalf. This process of developing meaning, claiming freedom, and taking on responsibility, however, was changing constantly with one's position and place in life. The emphasis given by existential theory to the ontological predisposition of the patient is the most fundamental and salient marker for human functioning, and is the lens through which one is viewed.

In Logotherapy, human problems are seen as arising in the form of neurotic anxiety that becomes attached either to the somatic, psychologic, or spiritual aspects of one's life. Frankl gave special attention to the spiritual neuroses, those that arise from existential concerns as opposed to those arising from intrapsychic conflicts. Frankl had great faith in and hope for the capacity of humans to rise above these anxieties. His accounts of life as a prisoner resonate with examples of tremendous human resilience and surprising capacity, of the common man or woman, to transcend the spiritual emaciation and weakness that so often is associated with human suffering.

Frankl bemoaned that spirituality, the experience which is so central to human experience, was ignored by Freud and his followers. He believed that it was from the spiritual sense of humankind that consciousness arose, and in a corresponding fashion, Frankl identified not only an instinctive unconscious, but a spiritual one. By the process of uncovering the spiritual unconscious, esthetic awareness, love, and life values arose.

The will to live in the face of death, the will to hope in the presence of hopelessness, and ultimately the "will-to-meaning" in the presence of meaninglessness were the basis for psychotherapeutic applications of existentialism. Thus, Frankl's goal in psychotherapy was to help patients find meaning and responsibility in life independent of their life's circumstance. In an attempt to help "ground" his patients, he would often ask, "Why do you not commit suicide?" (Frankl, 1963). From their responses, he would seek the emotional basis for their existence.

True to the phenomenological assumption that characterized all of the experiential system, Frankl placed trust in the struggles of lost or searching patients to find a meaning from which to extract the basis for existential preservation; personal elements and experiences with which to illuminate the meaning in their lives. For some, meaning may be found in love for family; for others it may be in a relationship with a church or organization. Whatever the scenario, the intricate and delicate processes of a therapeutic search for meaning involved in the integration or weaving together of these threads of broken lives into a supportive pattern.

6.07.2.2 Phenomenological Approaches: The Rise of Client-centered Therapy

Like existentialism, client-centered therapy had its roots in religious tradition and practice. However, whereas existentialism arose from religious persecution and was supportive of contemporary religious views, the Client-centered movement began as a reaction against the attitudes and philosophies that characterized much of American Protestantism.

Carl R. Rogers (1902–1987) was raised in a close-knit, Methodist family that was committed to the Protestant traditions of work and obedience. He struggled with the religious dogmas of his family, most of which seemed arbitrarily to dictate how he should feel and what he should do. He viewed these dictates as constraining both of his intellectual growth and of his enjoyment, and found little comfort in the admonition that they should be accepted on faith alone. When, as an adolescent, his family moved to a farm, Rogers became enthralled with the science of agriculture. He devoured articles and books describing agricultural research and, deriving support from the dictums of science, he began to question his family's religious traditions. He found in science the hope that abstract principles and assumptions could be put to a test. He also found hope for an escape from unbending religious doctrines. Eventually, the development of a nondirective, nondoctrinaire approach to helping people was his escape from the rigid views of a conservative "(almost fundamentalist) Protestant Christianity" (Rogers, 1959, p. 184).

The route to the development of client-centered therapy passed through a number of stages as Rogers grappled with how to reconcile his scientific need for structure, his personal needs for freedom, and the dogmatic and controlling religion of his youth. Rogers originally called his approach to psychotherapy "Non-directive," a reflection of his de-emphasis on therapist authority. Later, he adopted the term "Client-centered" (Rogers, 1951) to place the focus on the process rather than the techniques. In later years, Rogers came to prefer the term "Person-centered" to reflect his evolving interest in the application of his ideas to environments beyond that of psychotherapy.

In adolescence, Rogers felt distant from the family religion, a distance that was exacerbated by the liberal views to which he was exposed at the University of Wisconsin, where he graduated with a B.A. degree in 1924. Still trying to maintain a foothold in religion, upon entering young adulthood, he sought out a liberal Christian denomination and undertook studies as a minister in the Union Theological Seminary. He found there a religious environment that gave him both the opportunity and the encouragement to engage in free, philosophical thought. This freedom of thought, however, ultimately moved him even further from his religious roots and he left the seminary after two years in order to enter the graduate program in clinical psychology at Columbia University's Teacher's College.

Rogers graduated with an M.A. (in 1928) and a Ph.D. (in 1931), but during these years his break with formal religion became complete and he began to seek other avenues for expressing his humanistic values. Client-centered Therapy may well have been his long-sought alternative to religion in providing meaning and structure in his life.

Rogers initially was encouraged to work with children and families, probably because in these prewar years this domain still offered the only significant opportunity for a nonphysician to offer treatment. In 1928, when he was nearing the completion of his Ph.D. work, Rogers was accepted as a Fellow at the Child Guidance Center in Rochester, New York. Here, he was exposed to a deeply ingrained Freudian viewpoint. He found the rigidity of this viewpoint at contrast to the free-thinking environment that had first attracted him to Union Theological Seminary, and reminiscent of the religion of his youth. Like religion, he found the speculative and nonempirical nature of Freudian methods to be remarkably at odds with the statistical and methodological rigor that characterized both the agricultural science of his youth and the curriculum at Teacher's College. Ultimately, he rejected the rigidity of Freudian dogma as he had rejected fundamental Methodism. In what was a compromise between the contrasting values that he held, at once favoring structure and needing freedom, he adopted the structure of the scientific method as a means of demonstrating the value of his freedom-giving psychotherapy procedures.

After completing a Ph.D. degree from Columbia Teachers College, Rogers continued as a staff member and Director of the Child Study Center as it merged with the University of Rochester. He spent nine years in this position, ending his tenure there in 1940. During these years, America was in heated debate about entering the European war. Scant attention was given to other social ills. Rogers found that his interest in and work as a psychotherapist were not given great value either by his academic colleagues or by the courts and schools that purported to rely on psychological services. Yet, in the midst of an eclectic and supportive group of colleagues in Rochester, he began to formulate his ideas and to conduct experiments on the effectiveness of his nondirective methods.

Rogers became familiar with the controversial works of Otto Rank, and with that of Rank's devotees at the Philadelphia Child Study Center, and this work left its mark on Rogers. On the one hand, he found these approaches to be challenging because they forced him to search for and to find the order that he suspected to exist in clinical work. On the other hand, the stranglehold that psychoanalytic views held on clinical practice prevented his receiving the encouragement and assistance he needed to conduct research on his evolving theories. This led him to seek an academic environment in which he hoped to find more support for his research interests.

Rogers took a position in the Department of Psychology and at the University Counseling Services at Ohio State University in 1940. His hopes that his evolving theory and research program were allied closely enough with experimentally based views of behavior to earn him support from colleagues in this environment proved to be frustrated. These were the war years, a time when the concepts of personal freedom were highly valued, but the encouragement of constraint, control, and obedience were also of signal concern. Devotion to personal freedom, a concept that represented a national mantra during that time, synergistically attached itself to Rogers' own history of constraint and structure. The product was a unique form of psychotherapy that valued freedom, that saw an environment (including a therapy environment) that reduced structure and authoritative demands as the avenue for its realization, and that, paradoxically, sought evidence of its value through the structure and rigor of the scientific method.

At Ohio State University, Rogers discovered that his notions of the subjective were at odds with the rigid laboratory science of psychology that held sway in academia, however. It was through this experience that Rogers became convinced that his theoretical perspectives, indeed, represented a new direction in psychology. His ideas flowered while he was in Ohio, but the fruit emerged later, while he was at the University of Chicago (1945–1957).

WWII opened the door for psychologists to provide services to adults. The needs, both for mental health treatment and for vocational guidance, that were exacerbated as veterans reentered society at the end of the war, became the means for counseling and clinical psychology to separate from school and child psychology, and to enter the world of adult mental health. Correspondingly, Rogers found his niche at the University of Chicago Counseling Center, where he served as the Executive Secretary and Director and enjoyed the richness of working with individuals of varied backgrounds. He taught students of psychology, theology, education, human development, and sociology, and carried on a practice that included work with veterans, families, and young adults. His teaching was supplemented by the responsibilities and excitement of a patient/client load that consumed 15–20 hours per week. It was during these years that client-centered Therapy caught the imagination of the field and became firmly established within clinical and counseling psychology.

In 1957 Rogers returned to his alma mater, the University of Wisconsin, where he was to serve on the faculties of both psychology and psychiatry. His research continued to earn widespread recognition there. His ideas caught on and widely dispersed research groups began developing and refining his ideas. Research on therapist-offered conditions promised both to establish psychotherapy's empirical base and provide a bridge across various theoretical points of view.

In 1962, Rogers became a Fellow at the Center for Advanced Study in the Behavioral Sciences at Stanford, California. By this time, his interests in applying the client-centered approach to group therapy were well entrenched and his ideas were expanding to include community relations, education, and other nontherapy environments. To foster these "person-centered" ideas, following his year at Stanford, Rogers became a Resident Fellow at the Western Behavioral Sciences Institute in La Jolla, California. He went on to found and direct the Center for the Studies of the Person there, and remained in that position, as Founding Fellow and Resident Fellow, until his death in 1987 (Patterson & Watkins, 1996).

As might be guessed from his history, Rogers was preoccupied with establishing the science and the practice of psychology as an integrated discipline. Writing in 1959, he summarized the relationship between science and practice in very contemporary terms. He asserted that while research and theory share the common goal of bringing order to experience, their methods frequently are incompatible. However, he maintained that scientific knowledge can come from clinical observations as well as through controlled research; in fact, naturalistic observation is frequently the first step in empirical research. He considered traditional controlled research paradigms as being too simplistic to understand the complex variables that affect human growth in psychotherapy. Rogers observed that a progressive and helpful science capitalizes on serendipity and chance; it captures in unexpected moments kernels of truth that cannot be preordered on demand within the laboratory.

Finally, he urged that the book should never be closed on any theory. Since every theory contains an unknown element of error, no theory is ever completely valid or invalid. The role of research is to see beyond the dogma of theory and search for the nuclear truths that were germane to and common among all theories and that transcend the clinic, the laboratory, and even the discipline of study. While phenomenological understanding was necessary on the personal, therapeutic level, understanding the nature of this phenomenological truth would require the objectivity of science. The structure of science provided the best available protection against self-deception.

The structure of personality and the nature of adaptation outlined by client-centered therapy is found in the concept of the "self" (Rogers, 1951; 1961). The emergence of Self as a viable explanatory concept provided a base from which the therapist could justify a personal identity in therapy and could directly encourage and foster personal choice on the part of patients and clients.

In its focus on choice and freedom, client-centered therapy revealed its roots, not to be in existential crises, but in a reaction against controlling and oppressive religions that threatened moral choice and self-governance. Unlike Frankl, to Rogers the threat was not to physical existence and humanness, but to mental and moral autonomy. The correction was not to move closer to the mysteries of spiritualism and subjectivity, but further away, clearly reflecting the different religious experiences of the two authors. While Frankl found solace in religious philosophy, Rogers found it constricting. But client-centered therapy, no less than the whole of existential approaches, offered both a positive view of growth and hope for freedom from mental domination. Client-centered therapy added psychotherapy research methodologies to the other important and respected methods used by other humanists to understand the processes of change.

The essence of client-centered therapy was summarized in Rogers (1993/1997) classic paper, "The necessary and sufficient conditions of therapeutic personality change." Though subsequently criticized for assuming an all-important position as both necessary and sufficient (Lambert, 1991), variations of these qualities have been adopted by most therapeutic approaches as, at least, "highly desirable." The conditions emphasized the importance of an emotionally congruent therapist who is able to convey empathic understanding and positive regard.

While frequently interpreted as being a philosophy only about therapist qualities, in truth, Rogers offered, in these principles, a view that included the patient variables and perceptions in creating necessary conditions for change. Specifically, he identified patient distress or incongruence as a motivational construct. This anxiety complemented the natural growth processes by providing the impetus to work and to engage the therapist.

There were other patient qualities hidden in Rogers' treatise as well. For example, he asserted that the patient must perceive the therapist's empathic understanding and regard, implying that a degree of interpersonal facility and competence, as well as a capacity for realistic interpersonal appraisal, are necessary for effective work. In later explanations, it became clear that Rogers was not suggesting that this therapy would be ineffective with those who lacked these skills, but that all individuals had the capacity for the level and type of sensitivity that would allow them to benefit from a therapeutic environment. In his later book, *On becoming a person*, Rogers (1961) revealed his ties to existentialism and humanism as a method of understanding, as a set of assumptions about the nature of human problems, and as a philosophy about the causal locus of change (Rice & Greenberg, 1992).

The famous Rogers–Skinner debates (Kirshenbaum & Henderson, 1989) highlighted Rogers' beliefs in personal choice and emphasized the value he placed on the patient's responsibility for their own change experiences. While considering the locus of change to be within the person, he asserted that free choice could only be expressed when certain environmental events and conditions are present. The therapeutic environment was designed to consist of those contextual conditions. The therapist's sensitive support and the client's willingness to explore work synergistically to foster the conditions for growth.

6.07.2.3 Humanistic Approaches: The Rise of Gestalt Therapy

Gestalt psychotherapy took root as a counter-response to the negativism of psychoanalysis. It was a logical extension of the movement toward personal direction and freedom that characterized Logotherapy and client-centered therapy. It did so, however, without relying on the abstract concepts of spirituality of these former approaches. Although the emergence of Gestalt therapy is generally thought to have been in the postwar years of the 1940s, its genesis actually was some 20 years earlier.

Friedrich (Fritz) Perls (1893–1970) was born in Berlin (Patterson & Watkins, 1996). He obtained an M.D. degree from the Frederich Wilhelm University in 1920. Following his medical training, Perls worked under the direction of Professor Kurt Goldstein at the Frankfurt Neurological Institute for Brain-Damaged Soldiers. With the advent of WWII, Perls took his family to South Africa and in 1935, he established the South African Institute for Psychoanalysis. In 1946, he emmigrated to the US having become disillusioned with the arise of apartheid in South Africa.

By training, Perls was a psychoanalyst, but he was heatedly dissatisfied with the dogma and structure of psychoanalysis. He was also influenced by the experimental work of Kohler, Wertheimer, and Lewin, with whose work he gained familiarity during his early years in Germany. Other existential philosophers with whose work he also became familiar also eventually affected his work, but initially he was too preoccupied with orthodox psychoanalysis to assimilate their work (Perls, 1947). Perhaps this is why he came to identify more closely with psychology than with psychiatry.

Fritz Perls met Laura Posner in 1926 while she was working on her Ph.D. in psychology. She was to become his wife and cofounder of Gestalt therapy. Laura Posner Perls' family was very affluent and culturally enriched, while Fritz was from a lower middle-class Jewish family. These class distinctions were to influence their relationship for many years.

Laura Posner Perls was heavily influenced by Martin Buber and Paul Tillich who were prominent contemporary existentialists. Laura and Fritz Perls worked closely together for nearly 25 years until they separated in the 1950s. Fritz Perls wrote his first book *Ego, hunger and aggression* subtitled "A Revision of Freud's theory and Method" in 1941 and 1942 while serving as a captain in the South African Medical Corps. Although it was not for many years that the name and character of "Gestalt therapy" was succinctly expressed, this first book introduced many of the Gestalt concepts which would later become central ideas in Gestalt therapy.

During the years that Fritz and Laura Posner Perls were together, Gestalt therapy was developing and maturing, although the particular contributions of Laura Perls often are obscured in the available writings. Although Gestalt therapy was first introduced in the US by Fritz and Laura Perls, it was not until Fritz found a home at Esalen Institute at Big Sur, California, in the 1970s that Gestalt therapy was recognized nominally as an independent theory. It was Fritz, not Laura, who came to be recognized as the discoverer, the father, and developer of Gestalt therapy. His estranged wife, Laura Perls, was residing in New York City, outside the mainstream of the human potential movement which was beginning in

California. She published few papers, and her contributions to the theory and methods of Gestalt work were known only to a handful of people (Corsini & Wedding, 1989).

Those familiar with the work of Laura, and Fritz Perls note interesting differences in how they implemented Gestalt therapy. One of the most noted of these differences pertained to the dimension of control and permissiveness that they applied in treatment. Laura employed procedures that were characterized by apparent permissiveness, while Fritz's work emphasized therapist authority and control (Hatcher & Himmelstein, 1976).

The 1930s and 1940s were a dynamic time for Fritz Perls. He was heavily influenced by a number of prominent people including Wilheim Reich, who was Perls' analyst in the 1930s, Karen Horney, and Otto Rank. Horney was said to have directed the young and rebellious Perls to a very eccentric and rebellious Reich. Most notable in his influence was Reich, who introduced Perls to a theory of psychosomatic medicine that considered physical movement and symptoms as the body's armor against threat (Perls, 1947). The body work and physical techniques of Gestalt therapy was a product of this earlier association.

However, it was Freud's theory of psychoanalysis that provided Perls with a theoretical framework for all of his future thinking; despite their differences, psychoanalytic theory was the major foundation upon which Perls built his understanding of human behavior, and it was psychoanalytic theory that he used as a standard against which to evaluate his own emerging theory. In Fritz Perls' autobiography, *In and out of the garbage pail* (Perls, 1969), he makes the following comment on Freud, "Rest in peace, Freud, you stubborn saint-devil-genius," reflecting his own ambivalent attitude toward both Freud and psychoanalysis.

Gestalt therapy differs from other systems and models in a number of important ways. For example, Perls accepted psychoanalysis as a general theory from which his own view derived. However, he chose to omit certain aspects of Freud's theory from his own view, such as psychosexuality, the tripartite anatomy of the personality (id, ego, and superego), and the nature of the unconscious. As applied to technique, these omissions led Perls to emphasize *how* rather than *why*, and explored experience within the "here and the now" rather than the "there and then."

Another difference is in the value assigned to various bodies of scientific research. Gestalt therapy draws from a broader scientific literature than most systems of psychotherapy. It placed greatest value on research that describes the nature of perception and information processing, as well as from literature on defense and psychopathology. At the same time, traditionally it has eschewed psychotherapy outcome research. This priority of values contrasts with client-centered therapy, for example, that has always valued outcome research, but has given little acknowledgment to research on psychopathology and personality development.

Still another distinguishing aspect of Gestalt therapy is its adoption of a holistic view of behavior. It regards individuals as being inherently integrated; their behavior reflects an integrated system whose collective activity cannot be understood by simply viewing isolated acts or structures. This humanistic view is borrowed from Rank, whose concept of the "total organism" contrasts with the psychoanalytic view that separated mind and body and divided the psyche into discrete elements, for example, id, ego, superego, that engaged in a struggle for power over one another. Instead, Gestalt theory asserts that people struggle and experience conflict because of the difficulty of incorporating new information into perceptions based on old knowledge.

Finally, Gestalt therapy defined self-actualization in a manner that contrasted with other experiential approaches. Self-actualization was reflected in balance, differentiation, and integration of cognitive, sensory, and emotional systems, rather than a motive toward social goodness. The ability of conceptual systems to communicate was manifest in the concept of self-response-ability, that is, the ability to choose to be active and to overcome apathy. Rather than encouraging social compliance, as might psychoanalytic therapy, Gestalt therapy encourages social rebellion and individualism.

6.07.3 CONTEMPORARY DEVELOPMENTS

This section will summarize some of the most significant developments and extensions of existential, humanistic, and phenomenological traditions. Both in the interest of space and because time has resulted in an inevitable blurring of theoretical boundaries, no attempt will be made to maintain clear distinctions among these models. Existential theories have become more phenomenological and humanistic ones have become more existential. While some of the more visible theorists within these different systems will be mentioned no attempt will be made to be inclusive or exhaustive and detailed consideration to the fine distinctions among their points of view will not be given.

This will allow a summary of the more important findings from the research.

6.07.3.1 Theoretical Developments and Applications

6.07.3.1.1 Existential theories

Experiential theories have continued to expand, but probably at a lower rate than in their heyday of the 1970s. Theories have become more integrative of phenomonological, humanistic, and existential perspectives, and have been applied to an increasing array of problems, formats, and environments.

Because they did not arise from a single strand of philosophy, it is difficult to find a coherent direction of development that has characterized the evolution of existential therapy. Several major authors, both European and American (e.g., Boss, Binswanger, Bugental, May, Maslow, Yalom), have offered contrasting directions. The works of May, Bugental, and Maslow have been particularly forward-looking and serve as a representative view of the field.

Rollo May, a psychoanalyst by training and practice, probably is most responsible for introducing existential therapy to the United States (Rice & Greenberg, 1992). Along with Irvin Yalom, one of his major contributions (May & Yalom, 1984) was the blending of existential and phenomenological viewpoints. Adopting the phenomenological view, he believed that the personal experience of an individual person was the most important vehicle to knowledge and understanding, and emphasized that a person could be understood through their own experiences more adequately than through a therapist's theory about people (May, 1961; May & Yalom, 1984). Likewise, May thought that access to a patient's motivation for change was best obtained through an exploration of the meanings, ideals, and goals that directed their life.

May's perspective began with a fascination with anxiety and its meaning. This topic served as the basis for his doctoral dissertation in 1950 as well as for a major book, *The meaning of anxiety* (May, 1977) that was revised and reprinted several times. He saw anxiety, defense, and abortion of developmental progress as the inevitable products of conflict between goals and aspirations and the demands and constraints of reality. However, in a viewpoint that was reminiscent of Rogers and others, he maintained that anxiety was growth enhancing.

Pushing this point further, May launched an insightful and provocative attack against psychotherapy theory. He noted that psychotherapists, in the interest of effecting good therapy, observe and attribute meanings to patterns or mechanisms of behavior, using language and concepts that are constructed by their theoretical orientation. He pointed out that both the experience of and resolution of anxiety was often aborted by therapists and other observers when they construed the patient's experience in ways that forced it into line with their own conceptual frameworks.

The tendency of therapists to filter perceptions of the patient through a rigid lens of theoretical views clouded their ability to accurately perceive and relate to the patient. More importantly, it frustrated the objective of bringing the patient into contact with the anxiety, preventing self-knowledge and resolution. He pointed out that a rigid or dogmatic theory prevented the therapist from adopting a phenomonological perspective. The therapists' task is to separate themselves sufficiently from their own histories and dispositions to accurately perceive the meanings offered by a patient's own developmental history.

Perhaps May's major contribution was his piercing questions of fellow therapists. He provocatively asserted the possibility that what therapists view as an understanding of the patient is, in reality, a projection of their own self-reinforcing theory.

The foregoing is not to diminish May's contributions to experiential theory. May's vision was to understand how people become aware of their own growth and potential, that is one's "beingness" (May, Angel, & Ellenberger, 1958). It is this phenomenon of becoming aware of one's beingness that characterizes May's most frequently noted contribution to theory, the "I-Am" experience.

The definition of the "I-Am" includes the perception of what is real, but adds an awareness of some emerging or existent potential. Thus, a person exists in the present but with the potential to *become* (May, 1961). This dynamic aspect of self experience is central to the capacity to change; it is a precondition for their solution (May et al., 1958). The success of this solution, however, depends upon a therapist being able to help clients recognize and experience their own existence.

May's "I-Am" experience was so ontologically sound that it resonated through much of the existential movement. The value of his teachings seemed to help organize and guide the search for what Bugental (1976) calls the "lost sense of being." May's "I-Am" experience was incorporated by Bugental into what he called the "existential sense." Like May, Bugental identified existing or being alive as the fundamental concern of each human being.

Bugental, however, emphasizes that the striving for existence supersedes the mere act of being alive. It is a motivator that drives a person to become more vibrant and sensitive to life. This quest for more life was inextricably related to what he called the tragedy of the human condition, the inability both to recognize and seize opportunities for fuller living.

Bugental's concept of the "lost being" is a person who was invisibly crippled, blind, and deaf to their own state of needing (Bugental, 1976, 1987). This blindness to one's own state of emotional impairment represented a loss of the inward vision that made it possible to assess how well outer and inner experiences match.

Abraham Maslow was another major figure in blending existential and humanistic theory. His most noted contribution was his assertion of a jurisdiction for psychology which dealt explicitly with issues of growth, motivation, and creativeness (Maslow, 1968). His hierarchy of needs expressed his motivational theory and replaced the unimotivational concept of self-actualization, embodied in experiential theory, with a conception that arranged this drive within an array of more basic motives. The ultimate questions of, "Who am I?" and "What am I?" according to Maslow could only be answered by the individual asking the questions and proceeding through the hierarchically arranged answers.

Another contribution of Maslow's was his conceptualization of inner awareness as a process of "listening to the impulse voices" (Maslow, 1971). He proposed that failures in personal growth, such as neuroses, were conditions in which these "impulse voices" or "inner signal" became weak or disappeared altogether. With the inability to hear these signals, the person was incapacitated and became detached from their own essence.

Maslow envisioned the result of detachment to resemble a zombie, the experientially empty person, rather than an anxious person as proposed by others. Anxiety represented a level of being aware of disconnection, but complete disconnection included a lack of awareness of this disconnection. Maslow viewed the disconnected person as one who was empty, and believed that recovering the self must include the recovery of the ability to have and recognize these inner signals (Bugental, 1987).

One major implication of this theory was in the nature of obsessive and compulsive behaviors. The experientially empty person, lacking direction from within, turned to outer cues for guidance and reassurance of existence. This person relied on external cues, such as clocks, rules, calendars, schedules, agenda, and other people as a substitute for personal resources (Maslow, 1971).

6.07.3.1.2 Phenomenological theories

The persuasive power of Rogers' ideas, bolstered by ample research support (see Beutler, Machado, & Neufeldt, 1994; Orlinsky, Grawe, & Parks, 1994), ensured that the concepts of therapy process (therapist empathy, acceptance, regard, and congruence) have been absorbed into the body of psychotherapy. Virtually all schools of psychotherapy find common ground in the views that a helpful therapist is kind, respectful, caring, and understanding, the essence of the Rogerian "necessary" conditions. The differences between the views of these therapist contributions and Rogers' earlier views are twofold: (i) these factors are considered to be minimal rather than optimal conditions for change, and (ii) none are considered to be necessary or sufficient of themselves. While there are a few "pure" client-centered theorists remaining, most within this tradition have accepted these modifications to Rogers' original tenets.

Out of this perspective, the translation of Rogers' views over time are best embodied in extensions of his work to the broader domain of experiential therapy. The most prominent of these are represented by the writings of Laura Rice, Eugene Gendlin, and Alvin Mahrer. These authors have added several specific procedures and philosophies to the general framework of client-centered therapy. The major contributions of each of these writers, however, has been more often remembered for the technical procedures introduced than in the philosophical truths that they have added to understanding (Hart & Tomlinson, 1970; Wexler & Rice, 1974). Indeed, they all represent an emerging view that the therapist-offered conditions (empathy, warmth, positive regard, and congruence) are insufficient to assure change. Thus, they offer the beginnings of a technology to encourage and even to direct change (Rice & Greenberg, 1992).

By the mid-1970s, client-centered therapy had become widely used as both a group and an individual therapy. It was also becoming more cognitive. Information-processing theory was popular and there was a concerted effort to integrate these views with the workings of client-centered therapy (Patterson & Watkins, 1996). Laura Rice proved to be one of the leaders in this movement. She formulated the therapist's role as an assistant to the patient; together patient and therapist embarked on a process of learning to symbolize experience. Rogers had discussed at length the idea that one of the goals of psychotherapy was for patients to begin to symbolize experience that was outside of their awareness. Symbolization represents the process of bringing information into focus and consciousness by giving it mental representation. This occurred largely, though not exclusively, through words.

Rice (1974) proposed that symbolization was necessary in order to accurately process new information and suggested that this process could be facilitated by "Evocative Reflection." This technique involved efforts to reactivate emotional experiences by drawing the client's attention to key experiences. Then the client was asked systematically to process or talk through the experience in a heightened state of arousal. The emotional information was thought to be more easily recoded and integrated by maintaining a heightened state of arousal and this was, in turn, enhanced by emotion-focused reflections and focus.

Gendlin (1981) took the concept of focus a further step, increasing the attention given to client-centered therapy's affect on sensory experiencing. Gendlin's method of focusing (Gendlin, 1981) included the use of nonverbal exercises, such as directed imagery and magnification of multisensory systems, designed to heighten awareness of sensory cues that signaled the presence of emotional experience.

Gendlin (1969) defined focusing as the process in which people make contact with a special kind of bodily awareness known as the "felt sense." This felt sense was neither an emotion nor an intellectual emotional derivative (cognition). Rather, it was a bodily sense or intelligence by which the body directs the person to answers for personal problems. Moving through the six stages of focusing, emotional and cognitive awareness were thought to emerge as by-products (Gendlin, 1969). While Rice's conceptualizations moved client-centered therapy ever closer to cognitive conceptualization, Gendlin's moved it closer to existential and Gestalt perspectives.

Mahrer (1983, 1986, 1996) furthered this movement of client-centered therapy toward humanistic models, increasing its resemblence to Gestalt therapy. In Mahrer's Experiential therapy, the therapist and client both develop images, the therapist's being an effort to replicate that of the patient. Laying side by side, the patient's experience is recreated in the therapist's imagery and both attempt to focus and move closer to the source of intense sensory and emotional experience. Mahrer (1989) has attempted to manualize the key steps that a therapist and patient make in effecting his "Experiential Therapy," making this approach both more researchable and more easily applied than conventional applications.

The steps of Mahrer's Experiential/Humanistic therapy are constructed to provide an increasingly intense therapeutic experience (Mahrer, 1983). In this process, cognition and emotions are salient to the extent that they occur within this genre of client *experiencing*. Thoughts and feelings of the client are both accompanied and facilitated by focusing attention on bodily sensations. The key to unlocking the power of the therapy resides in the client's ability to allow these physical experiences to occur and to then give them meaning. In this process, feelings such as fear, anger, anxiety, excitement, gloom, as well as various cognitive postures such as confusion are identified as signals of the client's experience. Associations with these signals are then used to provide a landscape of meaning to the experiences.

6.07.3.2 Humanistic Theories

Integration has characterized the development of humanistic models of psychotherapy. It is no longer easy to identify a psychotherapy that is only humanistic. The infusion and cross-fertilization of cognitive therapy, experiential/humanistic therapy, and client-centered therapy, with traditional Gestalt therapy, for example, have produced a rich array of interventions and novel directions to the conceptualization and application of psychotherapy. When cross-bred with the active orientation of Gestalt therapy, the experiential approaches of Gendlin and Mahrer have emphasized phenomenological interventions within a provocative and therapist-guided medium. Some developments have highlighted the bridging of cognitive and experiential theories while others have highlighted differences between two somewhat different strands of experiential therapy, the nondirective, person-centered approach of Rogers and the process-directive Gestalt approach (Greenberg, Elliott, & Lietaer, 1994).

Drawing on classical client-centered theory, the person-centered approach regards the "relationship" as necessary and sufficient for therapeutic change; humanistic experiential approaches advocate the importance of an active, process-directive intervention and cognitive therapies focus on the role of conceptual structures in emotional dysfunction. The result is a number of approaches that stress active interventions that utilize emotional access to facilitate a change of perspective and the power of which is deepened within the context of a person-centered relationship.

These evolving experiential/humanistic models of therapy are applied in an increasing variety of formats. While most often used in an individual format (Greenberg et al., 1994), group therapy formats are practiced widely (Daldrup, Beutler, Greenberg, & Engle 1988), and there are guidelines for their application to marital/couples therapy (Greenberg & Johnson, 1988).

Focused Expressive Psychotherapy (FEP) is an integrated experiential method for resolving blocked affect that is based on Gestalt therapy concepts. FEP works with a full range of inhibited emotions such as anger, fear, joy, and sadness with a particular emphasis on the range of emotions that surround the blocked expression of anger (Daldrup et al., 1988). FEP, first attempts to access the client's schematic memory by directing attention to potential relationships in which these memories developed. That is, the client is directed to painful memories involving interactions with parents, spouses, children, and other significant members. Therapy is then designed to heighten the intensity and expression of emotion associated with the memories so that new schematic structures can be realized (Engle, Beutler & Daldrup, 1991).

Although FEP attends to a full range of emotions which may be blocked or inhibited in an individual, particular attention is given to the emotion of anger. FEP assumes a five-step process that identifies emotions, specifies targets, determines markers of their presence, implements experiments in change, and evaluates progress. The patient is actively engaged in all of these processes, but the therapist is responsible for leading them through the processes. The experiments are designed to facilitate full awareness of the emotion itself as well as its implications and genesis.

FEP assumes that there are no "good" or "bad" emotions, per force, but rather that emotions exist in all human beings. Why an individual chooses to react in a dysfunctional or enhancing way to a stressful event is reliant on how accessible they are to emotional and sensory experience and the internalized rules that govern their behavior. The influence of early experiences in childhood cannot be overlooked in the formation of emotional development and the way in which an individual will react in emotionally laden situations. If a child is unable to complete an emotional cycle, then the expression of this emotion (most notably, anger) will become frozen and part of the individual's "unfinished business."

In contrast to most forms of psychotherapy, FEP was designed to exert specific effects for individuals who tend to constrain and inhibit emotional expression, regardless of the specific symptoms manifest. Individuals who can identify the hurtful relationships and experiences that may have caused the inhibition of emotion and who can identify past and present relationships in which they are unable to express important desires are considered to be good candidates for this type of therapy.

Process-experiential therapy (Greenberg, 1994) represents a similar model to FEP, but places more emphasis on the integration of broadly-based nondirective (client-centered) relationship strategies with Gestalt therapy methods, and less emphasis on the role of enduring patient traits. In this approach, there is also an effort to integrate the interventions within a theory of cognitive–emotion relationships. This theory blends cognitive and experiential theory (Greenberg & Safran, 1987). It assumes that the barriers to healthy functioning result from (i) difficulties in finding words or images to symbolize experiences, and (ii) dysfunctional emotional schemes through which to interpret experiences. Accordingly, the goal of therapy is to enable client's to access dysfunctional schemas within a therapeutic environment in order to facilitate relevant schematic change (Greenberg et al., 1993).

In process-experiential therapy, the client and therapist interact on two different levels. The first level concerns the moment-by-moment effects that each of the therapist responses has following a client response. Accurate and empathetic understanding of the client's words and messages provide the client with a feeling of being understood and received by the therapist. It is anticipated that these therapeutic responses will allow the client to initiate work on increasingly more difficult and painful issues.

The second level on which the client and therapist interact is viewed as more "molar" than the first. In this level, the therapist attempts to enable the client to resolve the larger affective problems that present themselves as in-session therapeutic tasks. This requires emotional experiencing, which is facilitated by attending to the emotions and senses in-the-moment, under the assumption that so doing activates emotional meanings that are then subject to inspection and change.

Process-experiential therapy is considered to be most appropriate for use among ambulatory outpatients who are experiencing moderate clinical distress and symptomatology. It is not suited for clients with major thought disorder or schizophrenia, impulse control or antisocial personality patterns, or for those who may be in need of immediate crisis intervention or case management (e.g., acutely suicidal persons) (Elliott & Greenberg, 1995). It is not recommended for those who are unable to be self-reflective and those who find the therapist's nondirective stance of not advising or interpreting to be unacceptable.

6.07.3.3 Research and the Status of Experiential Therapies

The suspicion with which experiential therapies have traditionally regarded both diagnosis and empirical research has given way to produce an emerging body of scientific evidence. Led by the efforts to blend Gestalt therapy with client-centered and cognitive therapy, research has included both naturalistic studies, randomized clinical trials of patients in clearly defined diagnostic groups, and meta-analyses of contributors to efficacy. Findings from all of these research areas have generally supported the value of these approaches.

A prominent characteristic in the evolution of this research is the increasing focus on differentiating the client characteristics and problems for which experiential treatments are likely to be effective. Specific focus has been on clinical disorders such as anxiety disorders, major depression, and personality disorders. Some research has looked at broader dimensions than those identified by diagnosis, particularly focusing on the differential response of patients with different coping styles (internalizing and externalizing), levels of resistance, and those with physical symptoms.

Greenberg et al. (1994) summarized the results of studies conducted since 1978, using meta-analytic techniques. They compared pre- to postchanges on symptom measures and, where possible, compared treatment effect sizes to those observed among patients who were assigned to control or alternative treatments. They found moderate to strong effect sizes for experiential therapies, which compared favorably both with those observed among other therapies and demonstrated that these treatments were more effective than no-treatment and placebo-treatment groups.

Naturalistic and quasi-experimental studies have been used both to assess the relative efficacy of experiential therapy relative to alternative treatments (e.g., Beutler & Mitchell, 1981) and to assess the contributors to effective outcome within different types of psychotherapy (e.g., Burgoon et al., 1993; Greenberg & Foerster, 1996; Hill, Beutler, & Daldrup, 1989; Watson, 1996). Findings from these studies have suggested both that experiential therapies may be at least as effective as alternative treatments and that the level of arousal and experiencing induced by experiential methods facilitate the resolution of interpersonal conflict and reduce emotional distress.

Randomized clinical trial research designs have also incorporated various experiential therapies among the treatment comparisons. Especially promising results have been found in the treatment of those with depression using these controlled comparison procedures (e.g., Paivio & Greenberg, 1995). In a well-controlled investigation, Watson and Greenberg (1996) compared a Gestalt-based experiential therapy with a client-centered intervention, observing that while initial results were equivalent, long-term effects favored the more active experiential approach.

FEP (Beutler et al., 1987) has also been used successfully in the treatment of individuals who present with chronic organic pain. This domain of study is based on the theoretical connection between chronic pain and depression. Beutler, et al. (1987) undertook the task of testing the hypothesis that the intensity of pain correlates with the degree to which a person has persistent difficulty expressing anger and controlling intense emotions (e.g., Beutler, Engle, Oro'-Beutler, Daldrup, & Meredith, 1986). Using a multiple baseline design with six patients who had rheumatoid arthritis, Beutler et al. (1987) found that FEP substantially activated beta-endorphin discharge and correspondingly reduced depressive symptoms. This was particularly true in the early and late phases of treatment. However, the beta-endorphin response was not correlated with alterations of pain, suggesting that they functioned as stress markers more than as anesthetics of pain.

The evidence that certain "types" of patients are particularly responsive to experiential therapy has been the area in which the largest body of research has accumulated. Identifying clients by coping styles is another way of identifying a "type" of client who may benefit from experiential therapy. Whether a client is an externalizer vs. an internalizer may interact with the type of treatment that the client will receive. Beutler et al. (1991) found that those who coped with internalizing styles may profit more than externally-oriented clients in client-centered or nondirective therapies than from either cognitive therapy or Gestalt-based therapy (FEP). This has also been supported in several other studies that have used different approaches to identify or measure internalization. For example, Tscheulin (1990) reported that self-oriented clients (internalizers) did better with a nonconfrontational therapist than with a confrontational therapist.

Several studies (see Greenberg et al., 1994) have also concluded that high levels of client resistance is a contraindicator to the directiveness that is inherent in many experiential treatments, particularly those based on Gestalt/humanistic (e.g., FEP, process-experiential therapy) models. Specifically, highly resistant (high dominance, low submissiveness) patients do better in client-centered or nondirective therapies (Beutler et al., 1991, 1993) than in various directive, experiential therapies. In contrast, clients with low levels of resistance do better in these directive alternatives than they do in nondirective ones (Beutler et al., 1991). Although more research is needed on this general theme, the findings suggest that clients with good interpersonal interests and skills may be the ones who are most receptive to experiential therapies.

6.07.4 CONCLUSIONS

Experiential therapies comprise a heterogeneous collection of theoretically diverse interventions. They share certain assumptions about the nature of existence, the most reliable avenue to knowledge, and the mechanisms of symptom development and change. Humanistic, existential, and phenomenological traditions have had a long history within the fields of psychotherapy. Existential views emphasize the importance of personal meaning and choice in facilitating adaptation and survival in times of crisis; phenomenological approaches have emphasized the role of subjective experience, safety, and therapist-offered conditions as the avenues to understanding and change; and humanistic models have emphasized the role of active therapist interventions and the provision of structure in facilitating change.

Though deriving from different traditions, these models of behavior have merged over time, both in their theoretical development and in their methods of intervention. Central to these emerging, amalgamated theories is a common reliance on the concept of self as an organizing principle of personality, and on self-actualization as a foundation motivational principle.

Experiential models of behavior have historically observed that the "self" has been defined in Western cultures indirectly. Thus, one identifies him or herself through either occupational role (e.g., "I am a bus driver") or through some other external attribute or possession (e.g., "I am rich"). Experiential therapies pose the thesis that such definitions relegate self-definitions to the status of superficial attributes that can be threatened or destroyed by external change. The result is an identity that lacks stability and that is changeable and uncertain. The resulting construct of "self" comes to serve only the most tenuous of functions, and in this process projects a social image that is not authentic. Such reliance on superficial structures provides some limited protection from external threat but does not provide protection from the most basic of fears, the fear of nonexistence. Indeed, its presence makes one vulnerable to related fears of being irrelevant, ignored, and nonessential when these defining roles and possessions are no longer present.

Experiential therapies concentrate on redefining self-views, a process that is generally thought to be natural and orderly when environments are conducive. Thus, the specific therapy models that constitute the experiential tradition all seek to remove obstructions to these normal processes. By providing a permissive atmosphere, they attempt to facilitate and enhance normal movement toward differentiation of self, foster creativity, and stabilize personal identity. Specific theories of psychotherapy vary in the degree of directiveness exercised by the therapist (Perls vs. Rogers), in the roles they assign to spiritual and teleological drives (e.g., Frankl vs. Rogers), and to the acknowledgment of other motives (e.g., Maslow vs. Perls). However, they have in common efforts to focus patient attention on the moment, to encourage attendance to present sensory and perceptual impressions, and to expand therapist awareness of patient experience. While there is not now nor has there ever been absolute concordance among experiential models and therapists' theories, most have embraced this foundation principle.

Modern developments of experiential therapies have blended theories, often including principles and practices of cognitive and behavior therapies, as well as various components from humanistic, existential, and phenomenological viewpoints. There has also been a significant movement to reconceptualize human experience within a developmental perspective. In this conceptualization, emphasis is placed on growth as an immediately ontological experience, the person is a consciously and developing "being." These modern experiential therapies urge patients to focus both on immediate experience and on the progressive change and evolution of that experience as a way of obtaining self-knowledge. This view contrasts with both a static description of personal meanings and with models of behavior that emphasize either the effects of historical experience in their own right, the roles of unconscious drives, or the influence of biologically determined behaviors.

Traditionally, research has not been widely accepted in the experiential traditions. This is with the exception of Carl Rogers, whose client-centered therapy introduced the scientific method to the study of psychotherapy process and outcome. Led by active movements from client-centered and Gestalt traditions, however, there has been a proliferation of research. This research has sought both to specify and operationalize the application of experiential therapy so that they can studied objectively. The resulting manualized therapies have then applied these methodologies to the study of various clinical conditions. The resulting studies have found that experiential therapies produce modest and reasonably strong effects when compared either to patients' pretreatment status, control conditions, or comparison treatments.

Research also confirms that experiential treatments can be adapted to treat specific client disorders (e.g., depression, chronic pain, anxiety) as well as to a variety of client parameters. Research has been particularly fruitful in applying different aspects or tasks of treatments to different clients and situations. Therapists should be sensitive to the possibility that clients who are high in autonomy or reactance may react negatively to the effects of the more process-directive experiential therapies (e.g., Gestalt), whereas more dependent or externally oriented clients may react negatively to nondirective therapies. Likewise, experiential and nonexperiential traditions may be differentially effective for patients who vary in coping style. Experiential therapies may be most appropriate to those who are self-reflective, have organized cognitive processes, and who are capable of establishing stable interpersonal relationships.

Clearly more research is needed to study the effectiveness of experiential treatments. Research is especially needed that assesses treatment outcomes among specific populations and disorders. However, it is also important to direct research attentions to studies of the transfer of treatment to alternative settings, including research on methods of training, procedures to ensure the retention of therapeutic effects, and applications to populations that are generally unresponsive to other treatments.

6.08.1 INTRODUCTION

Over the past several decades, social skills training and problem solving training have become some of the most widely practiced techniques in clinical psychology, with applications spanning a broad range of adult disorders, and numerous books published on their theoretical foundations, clinical applications, and research (e.g., Bellack & Hersen, 1979; Hollin & Trower, 1986; Kleinmuntz, 1966; L'Abate & Milan, 1985; Nezu & Nezu, 1989; O'Donohue & Krasner, 1995b). Although various definitions of social skills have been given by different clinical researchers, Bellack and Hersen offer one of the most comprehensive descriptions of social skills as the:

> ability to express both positive and negative feelings in the interpersonal context without

> suffering consequent loss of reinforcement. Such skill is demonstrated in a large variety of interpersonal contexts and involves the coordinated delivery of appropriate verbal and nonverbal responses. In addition, the socially skilled individual is attuned to the realities of the situation and is aware when he is likely to be reinforced for his efforts. (1979, p. 512)

Problem solving can be defined as the ability to recognize problems or formulate goals, and to develop strategies to successfully reduce or eliminate the problem or to make progress towards achieving a goal. Training in social skills and problem solving generally refers to the systematic application of principles of social learning to the teaching of requisite skills hypothesized to underlie dysfunctions in interpersonal relationships, mood, and functional capacity (Davis & Butcher, 1985; Goldstein, 1982; Larson, 1984).

Skills training has a long history, and no single individual can be given sole credit for developing the method. However, several contributors to the development of social skills training should be noted. In the 1940s, Salter (1949) engaged individuals in role-plays in order to facilitate self-expression and to help them overcome symptoms such as depression and anxiety. In the 1950s, Wolpe incorporated role-playing into his approach to psychotherapy based on reciprocal inhibition. Wolpe (1958) theorized that assertive interpersonal behavior would be experienced as incompatible with feelings of anxiety, leading to the extinction of anxiety in certain social situations. Role-playing was used to help clients develop more assertive interpersonal skills. In the 1960s, Bandura's (1969) work on observational learning led to the formal inclusion of role modeling as a critical ingredient in social skills training. Also around this time, Lazarus (1966) introduced the use of repeated role-plays paired with instructions to facilitate the behavior-shaping approach employed in social skills training.

In their review of the history of psychological skills training, O'Donohue and Krasner (1995a) note several other key influences on the development of skills training which have played a prominent role in the emergence of behavior therapy as a system of psychotherapy. These influences include the concepts of behaviorism, instrumental and classical conditioning, social role learning, and finally social learning theory, which posited that deviant or maladaptive behavior could be learned, rather than being the product of a disease, leading to interventions designed to unlearn such behaviors or, as in the case of social skills and problem solving training, to teach more adaptive behavior. By the 1970s, the critical ingredients of social skills and problem solving training had begun to be packaged, and research was underway evaluating the effects of skills training on clinical populations.

Since the "packaging" of skills training procedures into standardized approaches, social skills training and training in problem solving have become some of the most widely practiced clinical techniques in individual, group, and family psychotherapy. Indeed, aside from clinical applications, the methods employed in skills training are widely applied with nonclinical populations as well, such as in work with maritally distressed couples (Gottman & Rushe, 1995), training parenting skills (Forehand & McMahon, 1981), and teaching employment skills (Berg, Wacker, & Flynn, 1990). Thus, although the focus of this chapter is on the application of skills training procedures with clinical populations, the principles of training can be used to teach skills to any desired audience.

This chapter begins with a review of theoretical models which serve as heuristics in understanding the impact of social and problem solving skills on interpersonal competence, and the effect of skills on the course of psychiatric disorders. Next, the fundamentals of assessing social and problem solving skills are described, followed by a review of the basic procedures for training skills. Different formats for training skills are then considered, including group, individual, and family-based approaches. Following this, different clinical applications of skills training are discussed, and research supporting the effects of training social and problem solving skills is reviewed. The chapter concludes with a brief summary of social skills and problem solving training for clinical populations.

6.08.2 THEORETICAL MODELS

Two different models have been proposed for understanding the impact of social and problem solving skills on adaptive functioning and the course of psychiatric disorders: the stress–vulnerability–coping skills model and the social skills model. These two models are compatible with one another, but each addresses a somewhat different domain of functioning. The stress–vulnerability–coping model addresses the relationship between social and problem solving skills, and the severity and the course of severe psychiatric disorders such as schizophrenia and bipolar disorder. The social skills model, on the other hand, addresses the relationship between social and problem solving skills, and functional capacity, including the ability to achieve desired goals. Both of these models are described below.

6.08.2.1 The Stress–Vulnerability–Coping Skills Model

This model provides a general framework for understanding the interactions between psychobiological vulnerability, psychosocial stress, and coping skills in determining the severity and course of psychiatric illnesses (Liberman et al., 1986; Nuechterlein & Dawson, 1984; Zubin & Spring, 1977). According to the model, psychobiological vulnerability is necessary for the development of a psychiatric illness. It is determined relatively early in life by factors such as genetic loading and early environmental contributions (e.g., insults to the fetus such as *in utero* exposure to the influenza virus or obstetric complications). Stress is defined as any environmental change or set of contingencies that requires adaptation to minimize noxious effects (e.g., the loss of support from a significant other, living in a stressful home environment, stressful life events). Stress interacts with psychobiological vulnerability, increasing the chances of either developing a psychiatric disorder, precipitating the occurrence of previously dormant symptoms in an individual who already has a psychiatric illness, or worsening symptoms in a currently symptomatic individual. Coping skills are those abilities that enable an individual to buffer the negative effects of stress on psychobiological vulnerability. Coping skills operate by either eliminating the source of stress (e.g., solving a pressing problem) or by decreasing the unpleasant effects of stress (e.g., talking about feelings with friends after the death of a loved one) (Lazarus & Folkman, 1984). Social skills and problem solving skills are examples of coping skills.

The stress–vulnerability model of psychiatric disorders has important implications for treatment. Although psychobiological vulnerability is assumed to be present at a relatively early age, it can be decreased by encouraging adherence to prescribed psychotropic medications and minimizing the abuse of substances which may exacerbate psychiatric conditions (e.g., alcohol, cannabis, cocaine; Drake & Brunette, in press). The negative effects of stress on vulnerability can be minimized in three ways. First, clients' exposure to stress can be reduced by modifying the environment in which they live (e.g., decreasing negative affect in the family environment; Dixon & Lehman, 1995). Second, clients can be taught skills for minimizing the noxious effects of stress (e.g., stress management skills; Meichenbaum, 1985). Third, clients can be taught social and problem solving skills to enable them to decrease stressors that impinge upon them (Liberman, DeRisi, & Mueser, 1989). Thus, social skills and problem solving training offer the promise of decreasing symptom severity and the course of psychiatric illness by enhancing the ability of individuals to manage stress effectively.

6.08.2.2 The Social Skills Model

This model addresses the relationship between social and problem solving skills on the one hand and social competence and social adjustment on the other (Bellack, Mueser, Gingerich, & Agresta, 1997). Social competence is defined as the ability to achieve desired goals. Social adjustment refers to an individual's actual attainment of those goals, including the ability to function in different social roles (e.g., worker, parent, spouse, student), to enjoy leisure and recreational activities, and to care for oneself (Mueser, Bellack, Morrison, & Wixted, 1990). The social skills model postulates four assumptions about the relationships between social skills and problem solving skills and social functioning:

(i) social competence requires the integration of a set of component behaviors;

(ii) impairments in component skills contribute to poor social competence;

(iii) social skills are learned or are learnable;

(iv) deficits in social and problem solving skills can be rectified by skills training.

As noted by Bellack et al. (1997) and discussed further in Section 6.8.3, social skills are not the only determinent of social functioning; a wide range of other factors may also influence social adjustment, such as psychotic symptoms, environmental conditions, and mood. However, skills are postulated to be critical ingredients for interpersonal success, and deficits in these skills can be rectified through skills training techniques. While the stress–vulnerability model addresses the interface between skills and psychiatric illness, the social skills model is aimed at explaining the relationships between skills, social functioning, and goal attainment.

It is beyond the scope of this chapter to review the wealth of evidence supporting the stress–vulnerability–coping skills model and the social skills model (e.g., Trower, 1995; Yank, Bentley, & Hargrove, 1993). The practical importance of these models is that they have served as heuristics for clinicians and researchers in understanding the roles of social and problem solving skills in social functioning, and the interaction between these skills and the course of psychiatric illnesses. Furthermore, these models have resulted in testable predictions about the effects of social skills and problem solving training on social adjustment in psychiatric disorders, predictions which have been empirically supported by research reviewed later in this chapter.

6.08.3 ASSESSMENT

This section discusses: (i) the components of social and problem solving skills; (ii) the range of strategies for assessing skills; (iii) nonskill factors which can influence social competence; and (iv) strategies for integrating assessment into treatment.

6.08.3.1 Components of Social and Problem Solving Skills

Prior to the late 1970s, social skills were broadly conceptualized strictly in terms of specific behaviors such as eye contact, voice tone, and the verbal content of what is said. However, in the late 1970s and 1980s, a number of different clinical research teams independently proposed a tripartite typology of social skills, which included social perception, cognitive (or problem solving) skills, and behavioral skills (McFall, 1982; Morrison & Bellack, 1981; Trower, Bryant, & Argyle, 1978; Wallace et al., 1980). Based on this broader conceptualization of social skills, social competence is conceptualized as requiring three different types of skills.

First, in order to be effective in a social situation, the person must be able to accurately perceive relevant situational parameters, such as their relationship to the other person, whether the setting is public or private, and the other person's affective response (i.e., social perception skills). Recognition of these situational features is crucial, as they may constrain the appropriateness of social behaviors. There is ample evidence showing that social perception skills, such as the inability to accurately perceive the facial expressions of others or recognize interpersonal problems, are correlated with poorer role performance in clinical populations (e.g., Bellack et al., 1994; Hellewell & Whittaker, 1998; Mueser et al., 1996).

Second, after the relevant social information has been extracted from a situation, the individual must be able to formulate a goal, generate possible response alternatives for achieving the goal, weigh the benefits and disadvantages of each possible solution, and choose the best solution. Although these cognitive skills may occur implicitly, they have an important bearing on the success of any plan, and hence are of direct relevance to an individual's social competence. In addition to the cognitive skills generally subsumed under the rubric of "problem solving skills," other cognitive skills can also influence social competence. Abstract thinking can be crucial for an individual to grasp a concept related to solving a particular problem or achieving a desired goal. Memory impairment may interfere with social competence by rendering it more difficult for individuals to learn from past mistakes or recall critical features of situations. Cognitive functioning has been found to be a robust predictor of psychosocial adjustment, with research suggesting that the ability to cognitively process socially-oriented information (i.e., social cognition) is especially critical to success in interpersonal spheres (Penn, Corrigan, Bentall, Racenstein, & Newman, 1997).

Third, after social perception and cognitive skills have been used to appraise a situation and formulate a plan of action, behavioral skills are required to carry out the plan. Behavioral skills refer to the actual behaviors emitted in interpersonal situations that are necessary to achieve a particular goal. Broadly speaking, behavioral skills can be divided into four different areas, including nonverbal components, paralinguistic skills, verbal content, and interactive balance. Nonverbal components are behaviors such as eye contact and use of gestures that convey meaning or affect during an interaction. Paralinguistic skills correspond to the vocal characteristics of speech, such as voice tone, loudness, and inflection. Like nonverbal components, paralinguistic skills often communicate vital information during an interaction, such as the speaker's mood or underlying motives.

Verbal content refers to what is actually said, regardless of the manner in which it is said. If the verbal content is difficult to understand, bizarre, or socially offensive, it will interfere with social competence. However, in most day-to-day interactions, nonverbal and paralinguistic skills are as important or more important than verbal content in determining a person's social effectiveness. Interactive balance concerns the reciprocity between two individuals in a social interaction. For example, the amount of time each person spends speaking, and the amount of reinforcement each speaker provides to the other when the other person is speaking, can influence whether a person experiences an interaction as rewarding. Thus, the interactive balance between two persons may partly determine whether either person desires similar interactions with the other in the future. Numerous studies have documented that the social behaviors emitted in interpersonal encounters, including paralinguistic features, nonverbal skills, verbal content, and interactive balance, are less effective in clinical populations such as schizophrenia than in nonclinical populations, and are correlated with social functioning (e.g., Bellack, Morrison, Mueser, Wade, & Sayers, 1990; Bellack, Morrison, Wixted, & Mueser, 1990). Table 1 provides a summary of the different components of social skills.

6.08.3.2 Assessment Strategies

A number of different strategies can be used to assess social and problem solving skills, including self-report, reports by significant others, naturalistic observations, and role-play tests (Liberman, 1982). Each of these strategies has advantages and disadvantages, and a combination of strategies is preferable (Curran, 1979; Wallace, 1986). It is usually best in clinical practice to combine at least two or more assessment strategies for identifying specific deficits in social and problem solving skills that will be the focus of subsequent training. Different assessment strategies are briefly described below, including the advantages and disadvantages of each approach.

Self-report measures of social and problem solving skills (e.g., Connor, Dann, & Twentyman, 1982; Rathus, 1973), based on either questionnaires or interviews, have the advantage of being easy to administer and score. In addition, assessments are helpful because they provide therapists with valuable insights into clients' perceptions of their own needs. Because of these distinct advantages, the assessment of skills usually includes at least some information from the client's point of view. Although self-report information is easily obtained, it often has limited validity, especially in clients with severe mental illnesses such as schizophrenia and bipolar disorder. An additional problem is that self-reports often lack the behavioral specificity necessary to target specific situations and behaviors for skills training. For these reasons, self-reports are of limited utility in the assessment of social and problem solving skills, although they are frequently obtained as an adjunctive measure.

Table 1 Components of social skills.

- Nonverbal behaviors
  - Eye contact
  - Facial expression
  - Posture
  - Use of gestures
  - Body orientation
  - Interpersonal distance
- Paralinguistic skills
  - Loudness
  - Tone
  - Pitch
  - Affect
  - Rate of speech
  - Clarity of speech
  - Duration of utterance
- Verbal content
  - Verbal message
  - Choice of wording
  - Appropriateness of self disclosure
- Interactive balance
  - Smoothness of turn-taking
  - Use of social reinforcers (e.g., reflective listening skills)
  - Balance of time-talking

Reports by significant others offer a number of advantages over self-reports of social and problem solving skills. Significant others often directly experience the consequences of poor skills in clients, and may be able to pinpoint specific situations in which these skills are most prominent. For individuals with psychotic disorders, reports by significant others also have the advantage of not being susceptible to the cognitive distortions and denials often present in persons with these illnesses. Despite these advantages, there are a number of limitations of these reports. Significant others are privy to only certain types of social interactions, and are thus unable to inform about clients' skills in many other situations. In addition, although significant others can often identify situations in which clients experience difficulty, their reports typically lack the level of behavioral specificity necessary to target skills for training. Therefore, reports by significant others are often useful for identifying problem areas and specific situations in which clients experience difficulties, which can then be the focus of more fine-grained behavioral analysis.

After self-reports and reports by significant others have identified problematic social situations, detailed assessments of specific situations can be conducted through the use of naturalistic observations and role-play tests. Naturalistic observations can be important sources of information for several reasons. First, by their very nature such observations have a high generalizability to the social environment which clients face. Second, naturalistic observations can be easily performed in certain settings in which clinical staff have regular contact with clients. Third, direct behavioral observations provide information at a level of specificity necessary for targeting behaviors in skills training.

Of course, there are also limits to the value of naturalistic observations (Foster, Bell-Dolan, & Burge, 1988). Only certain social situations can be readily observed by others, and some important situations are almost always unobservable (e.g., intimate communications, offers to use drugs or alcohol). A related problem is that the behavior of some clients may be reactive to the presence of an observer, rendering the observation less naturalistic than intended. Despite these limitations, naturalistic observations provide important information about the social behavior of clients in "real world" settings.

A final assessment method is the use of role-play tests for the assessment of social skills. Role-play tests involve the engagement of clients in a simulated interaction which may be recorded and later rated on different dimensions of social and problem solving skills. There are several advantages of role-play tests over other assessment methods. Because role-plays can be scripted to address specific problem situations, they can be used to assess behavior across a wide range of situations, including situations in which naturalistic behavior cannot ordinarily be observed. Because of the contrived nature of role-play tests, the responses of confederates can be scripted, permitting the comparison of a client's performance both with other clients as well as over time. A final advantage of role-play tests is that there is extensive research supporting both their reliability and validity. For example, role-play tests tend to be stable over time in the absence of social skills training, and are correlated with independent measures of more naturalistically observed social behavior as well as social role performance (e.g., Bellack et al., 1990; Mueser, Bellack, Douglas, & Morrison, 1991).

Probably the most significant limitation of role-play tests is the time and effort required to administer them properly. Additional persons need to be trained and on hand to participate as confederates in role-play tests or the therapist must be able to serve as the partner. Depending on the rigor necessary for the rating of social skills, extensive training may be necessary to obtain reliable ratings of skill in role-play tests. Aside from the effort involved in conducting role-play tests, another limitation is the fact that role-plays tend to provide information about whether a client is capable of performing a requisite skill, but not necessarily whether he or she will perform that skill when an appropriate situation arises. These limitations notwithstanding, role-play tests have been shown to be useful for assessing social skills across numerous studies, and are sufficiently sensitive to the effects of social skills training to show improvements consistent with predictions (Bellack, 1979, 1983).

In summary, each of the different strategies for assessing social skills has both advantages and disadvantages, and a combination of methods is optimal in most cases. Assessment usually begins with identifying general areas of dysfunction based on interviews with clients and significant others. Information gleaned from these interviews can then be used to specify situations for more specialized assessment, employing naturalistic observations and/or role-play tests to better characterize the nature of any behavioral deficits or excesses.

6.08.3.3 Nonskill Factors which can Affect Social Competence

Although social and problem solving skills are hypothesized to be important determinants of social competence and social functioning, not all impairments in social adjustment are the result of deficits in these skills. The recognition of other factors which can also affect social functioning is critical, since successful intervention may require attention to these factors in addition to, or instead of, social skills. These factors fall under the general categories of medication side effects, mood, other psychiatric symptoms, environmental factors, and cultural mores.

A number of medication side effects can interfere with social functioning (Kane & Lieberman, 1992). For example, akinesia is a side effect of antipsychotic medications, characterized by a diminution of facial expressiveness and use of gestures. Another common side effect of antipsychotic medications is akathisia, reflected by an inability to sit still and a need to pace. Both of these medication side effects can interfere with social functioning because they may either make it difficult for the client to be sufficiently expressive (akinesia) or have a distracting influence on social interactions (akathisia).

Problems with mood, such as depression, may result in clients not using social and problem solving skills that are in their behavioral repertoire. For example, positive affect has been experimentally demonstrated to facilitate creative problem solving (Isen, Daubman, & Nowicki, 1987). Depression, reflected by a sense of futility and hopelessness, may cause a person not to use critical social or problem solving skills during an interaction, or to give up pursuing interpersonal goals altogether (Marx, Williams, & Claridge, 1992). Anxiety can interfere with a person's ability to use skills that he or she is ordinarily capable of, or may result in the avoidance of situations relevant to achieving interpersonal goals. Similarly, intense feelings of anger or hostility may impede the ability of a client to use effective social and problem solving skills.

Other psychiatric problems may also contribute to poor social competence independent of social skill. One group of symptoms that can have a negative effect on social functioning is the negative symptoms of schizophrenia, such as blunted affect, anhedonia, asociality, and paucity of speech (Andreasen, 1982). For example, clients with a diminished capacity to experience pleasure (anhedonia) may fail to initiate interactions or use relevant skills because they lack the motivation to pursue personal goals (Blanchard, Bellack, & Mueser, 1994). Another group of symptoms that can interfere with social functioning are positive symptoms such as hallucinations, delusions, and bizarre behavior. Clients with prominent positive symptoms often experience difficulties in their interpersonal relationships because their tenuous contact with reality interferes with establishing a common ground of understanding, a necessary precondition for much human communication (Chadwick, Birchwood, & Trower, 1996; Fowler, Garety, & Kuipers, 1995).

Environmental factors can have a profound impact on the likelihood that clients will use skills that are in their behavioral repertoires. Similarly, environmental factors can also interfere with the acquisition of skills during social skills training, by either limiting the opportunity clients have to use particular skills, or by not providing sufficient reinforcement for using the skills in appropriate situations. For example, in some state hospital settings, clients are reinforced by staff for assuming the "sick role" (i.e., extremely passive behavior), and attempts to break out of this mold by more goal-directed behavior may be actively discouraged (Goffman, 1961; Wing & Brown, 1970). For another example, a depressed client who lives with a domineering spouse may be actively discouraged from becoming more assertive unless that spouse is involved in, understands, and accepts the treatment plan.

Finally, cultural mores can influence both social skill and social competence. Cultures may vary in the established norms for behavior based on factors such as gender, age, and relationship to others. Behavior deemed to be "unassertive" in one culture may be viewed as "normal" and desirable in another (Sue & Sue, 1990). Awareness of the cultural norms of the groups to which clients belong is critical in order to understand cultural factors contributing to what appear to be problems in social functioning.

6.08.3.4 Integration of Assessment and Treatment

Although the assessment of social and problem solving skills serves as the cornerstone for selecting target behaviors for intervention, ongoing assessment over the course of treatment is critical for evaluating the success of intervention. Improvements in the specific social and problem solving skills targeted for treatment can be evaluated through the use of role-play tests and naturalistic observations in some settings. The larger question of whether improved social and problem solving skills translate into better role functioning is best addressed through interviews with clients and significant others. More objective information may be obtained through the selected use of standardized instruments for evaluating social functioning.

6.08.4 TRAINING TECHNIQUES

There are two basic models which are commonly used to train social skills: the motor skills model and the problem solving model (Bellack, Morrison, & Mueser, 1989).

6.08.4.1 Motor Skills Model

The primary focus of the motor skills model is on training the specific component skills necessary for successful interactions through repetition and programming the generalization of skills to a variety of real-life situations (e.g., Bellack et al., 1997). The fundamental assumption underlying the motor skills model is that overlearning specific behavioral skills through practice in both simulated (role play) and real social situations will result in these skills becoming automatic in relevant situations. Improved social competence, according to the motor skills model, develops in a fashion similar to the way in which expert performance develops over the course of extensive practice, resulting in complex skills that can be performed without contemplating the necessary steps in advance (Ericsson & Charness, 1994).

6.08.4.2 The Problem Solving Model

The problem solving model also places emphasis on the importance of repetition for acquiring necessary social skills. However, according to this model, the generalization of social skills to novel situations requires cognitive or problem solving skills to be maximally effective (e.g., Liberman et al., 1989). Real-life situations provide a multitude of different challenges, not all of which can be anticipated and prepared for in advance. The basic thesis of the problem solving model is that if clients are able to systematically apply problem solving skills in order to formulate goals and deal with obstacles or problems in social situations, their social competence will be improved. Thus, in addition to training motor skills, this model incorporates problem solving training in order to improve the generalization of social skills to novel situations, to enable clients to overcome potential obstacles to achieving goals, and to develop alternative strategies when initial ones fail.

6.08.4.3 Common Learning Principles

Both the motor skills and problem solving models employ a common set of learning principles, based mainly on instrumental (or operant) and observational (or social) learning theories (Bandura, 1969; Skinner, 1938), to train new social skills. Modeling (demonstrating a skill in a role-play) is frequently employed to familiarize clients with the basic steps of targeted skills. Verbal reinforcement is generously used to encourage effort and to draw attention to particular component skills that were performed well in a role-play situation.

Shaping refers to the reinforcement of successive approximations to a goal. Social skills require the complex integration of a number of component skills. Typically, these skills are learned gradually over many role-plays and with much practice outside of the sessions. Therefore, in order to encourage clients to keep trying, and to recognize their progress in acquiring targeted component skills, behavior needs to be shaped gradually over time by providing ample reinforcement along the way.

Generalization is the ability to transfer a skill learned in one setting to another situation. In order for social skills training to improve social functioning, clients must be able to use the skills acquired in training sessions in real-life settings. Therefore, programming the generalization of skills to client's natural living environments is an integral part of social skills training. Some of the strategies employed to facilitate generalization include community trips for clients to practice skills on their own, homework assignments, and teaching significant others (e.g., family members, staff members) to prompt clients to use skills in appropriate situations.

6.08.4.4 Basic Skills Training Techniques

The basic techniques of social skills training are outlined in Table 2 and are summarized briefly here. More information about techniques for training social skills are available in a variety of books, including McFall (1976), Trower et al. (1978), Goldstein (1982), Kelly (1982), Hargie and McCartan (1986), Liberman et al. (1989), and Bellack et al. (1997). The table describes social skills training in a group format, although the basic techniques are the same when working with individuals.

In order to teach a new social skill, a rationale must first be established for the importance of learning this skill. A combination of strategies can be used to develop the rationale, including asking questions in the Socratic style (e.g., "Why might it be helpful to express a positive feeling to someone who has just done something for you?"), providing additional reasons for the importance of a skill, and exploring the relevance of the skill to clients' personal goals and circumstances. The therapist's most immediate goal is to harness clients' motivation to learn the new skill.

After the importance of a skill has been established, the therapist discusses the specific component steps of the skill. For example, the skill of "expressing negative feelings" can be broken down into the following five component behaviors: (i) look at the person; (ii) speak in a firm voice tone; (iii) tell the person what they did to upset you; (iv) tell them how it made you feel; (v) suggest how this can be prevented from happening again in the future. The importance of each component step of the skill is discussed (e.g., it is important to look at the person so that you can be sure that you have their attention when you speak to them). After discussing the different steps of the skill, the therapist demonstrates the skill in a role-play. Role-plays are planned in advance, are usually quite brief, and are based on situations that are both highly plausible and likely to be encountered by clients. Immediately following the role-play, the therapist obtains feedback from clients about which component steps of the skill were observed and the overall effectiveness of the therapist in the role-play.

When clients have had an opportunity to observe the therapist model the skill, one client is engaged in a role-play of the same skill, usually based on the same situation. The advantage of using the same role-play situation at this point of the training is that it minimizes the amount of work the client must do in order to achieve a successful performance. Immediately following the role-play, the therapist provides positive feedback to the client about which specific steps of the skill were performed well. A critical feature of social skill training is that the therapist always provides immediate, positive, and specific feedback following each role-play. This feedback serves to encourage clients' efforts for trying to perform the skill as well as specific reinforcement for behaviors that were done especially well.

After positive feedback has been provided, the therapist provides the client with corrective feedback, conveyed in a helpful, upbeat manner.

Table 2 Steps of social skills training.

1. Establish rationale for the skill
    - Elicit reasons for learning the skill from group participants
    - Acknowledge all contributions
    - Provide additional reasons not mentioned by group members
2. Discuss the steps of the skill
    - Break the skill down into three or four steps
    - Write the steps on a board or poster
    - Discuss the reason for each step
    - Check for understanding of each step
3. Model the skill in a role-play
    - Explain that you will demonstrate the skill in a role-play
    - Plan out the role-play in advance
    - Use two leaders to model the skill
    - Keep the role-play simple
4. Review the role-play with the participants
    - Discuss whether each step of the skill was used in the role-play
    - Ask group members to evaluate the effectiveness of the role model
    - Keep the review brief and to the point
5. Engage a client in a role-play of the same situation
    - Request the client to try the skill in a role-play with one of the leaders
    - Ask the client questions to make sure he or she understands their goal
    - Instruct members to observe the client
    - Start with a client who is more skilled or is likely to be compliant
6. Provide positive feedback
    - Elicit positive feedback from group members about the client's skills
    - Encourage feedback that is specific
    - Cut off any negative feedback
    - Praise effort and provide hints to group members about good performance
7. Provide corrective feedback
    - Elicit suggestions for how client could do the skill better next time
    - Limit the feedback to one or two suggestions
    - Strive to communicate the suggestions in a positive, upbeat manner
8. Engage the client in another role-play of the same situation
    - Request that the client change one behavior in the role play
    - Check by asking questions to make sure the client understands the suggestion
    - Try to work on behaviors that are salient and changeable
9. Provide additional feedback
    - Focus first on the behavior that the client was requested to change
    - Engage client in two to four role-plays with feedback after each one
    - Use other behavior shaping strategies to improve skills such as coaching, prompting, and supplemental modeling
    - Be generous but specific when providing positive feedback
10. Assign homework
    - Give an assignment to practice the skill
    - Ask group members to identify situations in which they could use the skill
    - When possible, tailor the assignment to each client's level of skill

Rather than providing negative feedback about component skills that were performed poorly, one or two suggestions are made for how the client could improve his or her performance in another role-play. In addition to giving verbal suggestions for how to improve performance in the next role-play, the therapist can also model the skill again, drawing the client's attention to specific component behaviors that are targeted for change.

When corrective feedback has been provided, the client is engaged in a second role-play with specific instructions to modify particular component behaviors. The same role-play situation is used as in the first role-play. The second role-play is followed by the same sequence of positive specific reinforcement, with initial emphasis on the component skills targeted for change, followed by corrective feedback. Typically, a client can be engaged in two to five role-plays of a skill, depending on his or her motivation and improvement over the role-plays. If verbal instructions and praise alone are insufficient to bring about behavior change in the role-plays, the therapist may use a variety of other teaching techniques such as supplemental modeling by the therapist, coaching (i.e., whispering verbal prompts to the client during a role-play), prompting (i.e., providing the client with nonverbal cues, such as hand signals, to modify his or her behavior during a role-play) (Bellack et al., 1997), or, for severely impaired clients, attention focused training (i.e., combining verbal cues for response with primary reinforcers such as food) (Massel et al., 1991). The most critical concern when engaging a client in a series of role-plays is that he or she demonstrates some improvement in the targeted skill from the first to the last behavioral rehearsal. This is the essence of the shaping process, in which role-plays provide learning opportunities to improve performance over multiple trials.

After sufficient progress has occurred over the role-plays (and other clients have had the opportunity to practice the skill in similar role-plays), the therapist develops a homework assignment for clients to practice the skill on their own. The rationale for practicing the skill outside of the session may need to be reviewed with the client. Homework assignments are most effective when a specific situation to practice the skill can be identified by the client and therapist in advance. Possible obstacles to completing the assignment should be anticipated. When possible, significant others should be informed of the homework assignment so they may remind or prompt the client to practice the skill in appropriate situations.

The preceding sequence describes the introduction of new skills in social skills training. Usually several sessions are spent teaching one specific skill before moving onto another skill. Following the introduction to a skill, subsequent sessions begin with a review of homework, including the identification of situations where the client has unsuccessfully tried to use the skill or could have used the skill but did not. Instead of getting a description from the client of what happened, the therapist engages him or her in setting up the role-play of that situation. Following the role-play, positive and corrective feedback are provided using the principles previously described. Role-plays from more than one situation can be practiced, as well as situations that the client expects to encounter or hypothetical situations. Practicing the targeted skill across a variety of role-play situations, as well as trying the skill in real-life situations, serves as a form of generalization training. When the client has demonstrated an ability to perform the skill spontaneously in real-life situations, additional skills are introduced and trained.

6.08.4.5 Problem Solving Training

As in social skills training, training in problem solving skills involves following a specific sequence of steps (D'Zurilla & Goldfried, 1971). These steps are designed to allow consideration of as many solutions as possible and to consider what is needed in order to put a chosen plan into action. While social skills training focuses on teaching specific component behaviors necessary for effective interactions, problem solving training aims to teach a process for approaching problems and achieving goals. The process of problem solving has been likened to the scientific method (Kuhn, 1970; Popper, 1979), in which the essential task is to educate clients how to think and approach psychological problems in a more systematic, rational, and empirically based manner (Beck, 1976; Ellis, 1962). Thus, while social skills training tends to be content-oriented, training in problem solving is oriented towards teaching a set of processing skills designed to maximize goal attainment.

The basic steps of problem solving are outlined in Table 3 and are briefly described here. Further information about problem solving training can be found in a variety of books and book chapters, including Falloon, Boyd, and McGill (1984), D'Zurilla (1986), Hawton and Kirk (1989), Nezu, Nezu, and Perri (1989), and Mueser and Glynn (1995). The same steps of problem solving listed in the table are followed when teaching in an individual, group, couple, or family format.

Prior to the initiation of problem solving training, the therapist endeavors to develop in clients a problem solving "orientation" in which problems are viewed as obstacles which can be overcome or improved upon by systematically exploring and trying different response options. Similarly, achieving short- and long-term goals is construed as requiring individuals to overcome a series of obstacles which are ordered in logical sequence. The development of a problem solving orientation can be facilitated by providing examples of problems and their solutions, and reviewing the steps of problem solving. However, in the long-run, clients learn to adopt a problem solving orientation through repeated prompting, practicing the steps of problem solving on personally relevant problems, and experiencing the natural consequences of implementing effective solutions to their problems.

Problem solving begins with the identification of a problem or goal that the client wishes to resolve or achieve. As the definition of the

Table 3 Steps of problem solving.

Step 1: Define the problem
- Get different opinions about the nature of the problem
- Define the problem or goal in behaviorally specific terms
- If the problem is shared by more than one person, make sure each one agrees on the definition

Step 2: Generate possible solutions to the problem
- Brainstorm as many different solutions as possible
- Do not evaluate any solutions at this time
- Be creative and include "wild and crazy" ideas

Step 3: Evaluate the solutions
- Consider the advantages and disadvantages of each solution for solving the problem
- Systematically evaluate one solution at a time
- Avoid settling on one "best" solution before reviewing all solutions

Step 4: Select the best solution(s)
- Select the solution that seems most likely to be effective
- Consider how difficult the solution will be to implement
- Choose more than one solution if they can be easily combined

Step 5: Plan on how to implement the solution(s)
- Consider what resources are needed to implement the solution (e.g., money, skills, information)
- Anticipate possible obstacles to implementing the solution
- Establish a time frame for implementing the solution(s)
- If more than one person is involved, establish specific tasks for each person

Step 6: Review problem solving plan at a later time
- Plan a time to evaluate whether the problem solving plan was successful
- Do additional problem solving and modify the plan if the desired goal has not been obtained
- Praise all efforts at solving the problem, even if the problem is not entirely resolved

problem is crucial to the solutions that will be generated and likely success of solving it, the problem should be discussed in detail, and questions should be posed such as "Why is it a problem?," "For whom is it a problem?," and "How have you tried to solve this problem in the past and what happened?" If problem solving is conducted with others who may be invested in the problem and its solution (e.g., family members), then multiple perspectives on the problem are sought to ensure each person's involvement. When the nature of the problem or goal has been considered, the client must arrive at a specific definition of the problem. In general, the more behaviorally specific the definition, and the more circumscribed the problem, the greater the chance of solving the problem. Large, complex problems and ambitious goals are best approached by breaking them into smaller, more manageable chunks, each of which is the focus of problem solving. For couple- and family-based problem solving, all involved persons must agree on the definition of the problem in order for them to be involved in its resolution (Falloon et al., 1984).

When a problem or goal has been articulated, multiple solutions are identified for solving the problem or achieving the goal. Clients are urged to be as creative as possible at this point of problem solving, and to avoid editing, censuring, or evaluating any of the solutions that come to mind. Instead, all solutions are acknowledged, with the expectation that suggesting even bad or inappropriate solutions may lead to the identification of novel and innovative strategies. Clients who tend to be overly self-critical and punitive may require extra practice at not immediately rejecting solutions as soon as they are generated.

After a variety of possible solutions have been identified, each one is systematically evaluated in terms of its perceived effectiveness for solving the problem. This evaluation can be standardized by routinely assessing the advantages and disadvantages of each solution. Following the evaluation of solutions, the best solution or combination of solutions is selected. Often, the best solution is quite evident after the advantages and disadvantages of each solution have been considered. Sometimes no one solution is obviously best, more than one solution appears equally effective, or, when more than one person has a stake in the problem, there is disagreement as to the "best" solution. In such cases, the best solution is determined by combining different solutions, selecting more than one solution to implement, and determining which one should be tried first, or creating a new solution drawn from the previously discussed ones.

Solutions to problems can only be effective if they are implemented. Furthermore, a variety of obstacles can conspire to interfere with the implementation of a potentially effective solution to a problem. Therefore, planning on how to implement the solution is critical to successful resolution. Several factors are useful to consider when determining a plan for solving the problem. First, if more than one person is involved in solving the problem, roles for implementing the solution need to be agreed upon. Second, the resources needed to implement the solution must be evaluated, such as money, expertise, information, or skills. Role-plays may be useful at this stage to help clients develop or practice the requisite skills for enacting a solution. Third, possible obstacles to effective implementation should be explored and, if realistic obstacles are identified, tentative plans for dealing with them should be determined. Finally, a time-frame should be established for putting the different steps of the solution into action. This time-frame should include a follow-up time during which the success (or lack thereof) of the problem solving plan can be reviewed.

Although some problems are solved after a single attempt at problem solving, many are not, and it is common for repeated efforts to be required to make sufficient progress at resolving a problem or achieving a goal. An important part of developing in clients a problem solving orientation is conveying the idea that problem solving is often an iterative process that requires multiple efforts in order to secure success. In order to ensure that problem solving continues to be applied to problems that remain unsolved, it is helpful to establish follow-up times to evaluate the status of the problem or goal.

If the problem has been successfully resolved, then a new problem or goal can be targeted. On the other hand, if the problem remains, the therapist teaches the client how to systematically "debug" the problem solving plan. Finding the problem in a problem solving plan is accomplished by going through the steps of the plan in reverse order until a problem with the plan is identified, at which point the problem in the plan is corrected, and any necessary changes in the following steps are determined (Mueser & Glynn, 1995). Thus, the first step in debugging a problem solving plan is to determine if the solution was implemented as intended. If it was not, then the implementation plan needs to be altered in order to determine whether the selected solution will work. If the solution was implemented, but it did not work and the problem remains, then the second step is to re-evaluate the other possible solutions, and choose a different solution (or combination of solutions) for solving the problem. When a different solution has been selected, a new implementation plan must be made. If every solution has been tried and implemented, but the problem remains, the third step is to generate additional solutions for resolving the problem or achieving the goal, to then evaluate these new solutions, select the best one, and plan on how to implement it. Finally, if repeated attempts at solving a problem are unsuccessful and all viable solutions have been exhausted, a fourth and last step is to define the problem differently in order to increase the probability that the new problem will be more solvable than the old one.

6.08.5 FORMAT OF SOCIAL SKILLS AND PROBLEM SOLVING TRAINING

Social and problem solving skills can be taught in a variety of formats, ranging from individual psychotherapy, to group therapy, to couples or family therapy.

6.08.5.1 Group Skills Training

The group format is one of the most common formats for teaching social and problem solving skills. Skills training in groups generally follows a preplanned curriculum, which is provided over a limited time period, ranging from several months to over a year. Clients usually begin participating in the group at its initiation, and continue until the targeted skills have been acquired. Groups are often led by two therapists and comprise clients with deficits in similar areas.

There are several advantages to teaching social skills and problem solving in a group format. First, there is the obvious advantage of economy, considering that one or two therapists can work with five to eight clients simultaneously in a group setting. Second, group-based skills training provides clients with a variety of different role models, which may facilitate their acquisition of targeted skills. Third, feedback from other clients can be obtained in a group format, providing additional reinforcement for clients to practice the requisite skills. Fourth, group-based skills training can provide the opportunity for role-playing with a variety of different partners (i.e., different clients), a task which is much more difficult to accomplish when conducting individual psychotherapy. Fifth, clients often appreciate the opportunity of working with others who share similar difficulties and goals. For example, group-based social skills training can be conducted with individuals with severe mental illnesses (e.g., schizophrenia), social phobia, or poor assertiveness skills. Problem solving training in a group format offers the same advantages. Clients often enjoy being able to help each other make progress towards desired goals and appreciate knowing that they are not alone in the problems or obstacles they face. In addition, since most problems or goals that clients have are not unique, more than one client may benefit from progress made on problem solving about a particular goal.

6.08.5.2 Individual Format

Although the group format for skills training has a number of advantages, it is often not practical, especially for clinicians working in private practice. Social skills and problem solving training in an individual format follows the same basic principles as when working with groups. There are several advantages to individual-based work. By its very nature, it is easier to tailor treatment sessions to the specific needs presented by the client. There is also more time for training skills because of the exclusive focus on one client. Finally, skills training can be conducted on an *ad hoc* basis, rather than following a structured curriculum, which may be more beneficial for some clients participating in other types of psychotherapy, such as cognitive restructuring or relaxation training.

6.08.5.3 Family Format

Social skills and problem solving training can be conducted in the context of family or couples intervention. For example, behavioral marital therapy typically incorporates both training in basic communication skills for couples and problem solving skills as a strategy for minimizing conflict and increasing positive interactions (e.g., Bornstein & Bornstein, 1986; Jacobson & Margolin, 1979; Liberman, Wheeler, deVisser, Kuehnel, & Kuehnel, 1980). These interventions are based on the assumption that most of the difficulties maritally distressed couples experience are due to deficits in communication rather than fundamental differences in values and preferences.

Similarly, behavioral family therapy involves teaching basic communication skills and problem solving skills to family members (Mueser & Glynn, 1995). For example, Falloon, Boyd, and McGill (1984) developed a model in which families are taught four basic communication skills (active listening, expressing positive feelings, making positive requests, expressing negative feelings), followed by the six steps of problem solving. Families are taught communication skills following the same basic procedures used in the group format for teaching social skills, and are then given homework assignments to practice these skills on their own. Role-plays are used to assess family members' acquisition of targeted skills. When family members have demonstrated improvements in basic communication skills, they are then taught problem solving skills. Initially, the therapist leads the family to demonstrate the steps of problem solving. Subsequent to this, family members elect their own "chairman" to lead the problem solving discussion and "secretary" to record the family's problem solving efforts. The members are encouraged to have weekly meetings to practice their problem solving skills. Over time, as the family members' skills improve, increasingly more difficult problems are tackled, including problems that may be the source of major conflict between family members.

It is also possible to combine the group and family formats into a multiple family group format. For example, McFarlane (1990) has developed a model of multiple family group intervention for persons with schizophrenia and their relatives. In groups that are held every two weeks, problem solving is taught and regularly practiced in order to identify effective solutions to common problems, thereby reducing the risk of relapse and rehospitalization (McFarlane et al., 1995).

6.08.6 CLINICAL APPLICATIONS AND RESEARCH

Social skills and problem solving training have been applied to very wide range of psychiatric disorders and interpersonal difficulties. In fact, there are few areas of psychopathology or interpersonal dysfunction for which skills training approaches have not been developed. For example, skills training approaches have been developed to help people with problems such as anger management, interpersonal shyness and dating anxiety, poor assertiveness, conflict resolution, difficulties with interpersonal relationships on the job, marital discord, and dealing with social situations involving substance abuse. Although social and problem solving skill interventions generally focus on improving interpersonal competence in specific domains of functioning, programs are often targeted at groups of clients with specific diagnoses, including major depression, schizophrenia, borderline personality disorder, and social phobia, as well as individuals with developmental disabilities.

Table 4 summarizes clinical applications of social and problem solving skills training to different problem areas and populations. Many of the programs described in this table have been empirically validated in controlled studies. The research literature supporting the efficacy of social and problem solving training has grown rapidly over the last two decades, and these approaches now enjoy some of the best empirical support of all psychological interventions. It is beyond the scope of this chapter to critically review research on the effects of social skills training and problem solving training. However, numerous books and review articles are available that critically evaluate these different training programs, including Bedell and Lennox (1996), O'Donahue and Krasner (1995a), Dilk and Bond (1996), Benton and Schroeder (1990), Nezu and Nezu (1989), and Smith, Bellack, and Liberman (1996).

6.08.6.1 Utility of Social and Problem Solving Skills Training

From a treatment planning perspective, it is important to consider when skills training is a treatment on its own and when it best serves as an adjunct to other approaches to therapy. To some extent, the answer to this question depends on whether skills training is used to treat a complex constellation of behaviors and symptoms (e.g., a psychiatric disorder) or a more specific and narrower class of situations and behaviors. There have been numerous controlled studies of skills training for schizophrenia, with some evidence documenting benefits in the areas of social functioning, symptom severity, and relapses and rehospitalizations (e.g., Bellack, Turner, Hersen & Luber, 1984; Hogarty et al., 1991; Marder et al., 1996). Schizophrenia is a complex illness involving impairments across multiple domains, including social adjustment, cognitive functioning, and symptomatology. When skills training is conducted with persons with schizophrenia, it is provided in the context of a comprehensive treatment program (Bellack & Mueser, 1993), which may include a veriety of other interventions such as medication and symptom monitoring, case management, family psychoeducation, and vocational rehabilitation.

With respect to major depression, both social skills training and problem solving training have been shown to be effective in reducing severity of depression without the use of other interventions (Bellack, Hersen, & Himmelhoch, 1983; Nezu & Perri, 1989). However, in contrast to schizophrenia, where relatively few psychological interventions have been established to be clinically effective, a wide variety of therapeutic approaches appear to result in improvements in depression comparable to those produced by social and problem solving skills training, such as cognitive therapy and scheduling pleasant events (Dobson, 1989; Zeiss, et al., 1979). Therefore, skills training can be used as a primary treatment approach for depression, although its effects can be expected to be similar to those of other psychological interventions. In clincal practice, skills training is most often provided as an adjunctive intervention for some clients, in combination with cognitive or interpersonal therapy, rather than as the sole intervention.

Similar in some respects to its use in major depression, social skills training is frequently employed as an adjunctive strategy in the treatment of social phobia. For example, in a program for social phobia developed by Heimberg et al. (1990), cognitive therapy and exposure are combined with social skills training (role playing) in order to provide clients with feedback about their behavior, to challenge their distorted perceptions about their own social behavior, and to encourage them not to avoid feared social situations. Although some research suggests that cognitive therapy may not reduce social anxiety above and beyond that provided by the combination of social skills training and exposure (Hope, Heimberg, & Bruch, 1996; Stravynski & Shahar, 1983), other research indicates that cognitive therapy alone may be effective (Emmelkamp, Mersch, Vissia, & van der Helm 1985). However, in practice no single treatment approach is usually provided for social phobia; rather, most treatment programs involve a combination of strategies, including social skills training, exposure, and cognitive therapy (e.g., Heimberg et al., 1990; Turner, Beidel, & Cooley, 1994).

Social and problem solving skills training can be effective as treatments on their own (or in combination with training in other self-regulatory skills, such as stress inoculation, relaxation, cognitive restructuring) when they are provided to address a specific problem (or class of problems), often within a specific population (e.g., clients with developmental disabilities, psychiatric disorders). There are numerous studies in the research literature (some included in Table 4) of skills training interventions demonstrating superior outcomes compared with other treatment or waitlist (no treatment) comparison groups. For example, skills training has been found to be useful in decreasing problems related to anger (Benson, Rice, & Miranti, 1986; Deffenbacher, 1988), improving social anxiety, loneliness, and dating skills (e.g., Fox, McMorrow, Storey, & Rogers, 1984; MacDonald, Lindquist, Kramer, McGrath, & Rhyne, 1975), improving assertiveness (Gambrill, 1995), enhancing job-related skills, such as

Table 4 Examples of clinical applications of social and problem solving skills training.

Program developers	*Target population*	*Training format*	*Focus of training*[a]
Alberti and Emmons (1990)	Unassertive persons	Group	SST for skills to help people "stand up for their rights" and express feelings directly
Becker, Heimberg, and Bellack (1987)	Persons with depression	Individual	SST for interpersonal skills
Benson (1991)	Mentally retarded adults	Group	SST and PS to teach strategies for managing anger and interpersonal conflict
Falloon et al. (1984) Miklowitz and Goldstein (1997) Mueser and Glynn (1995)	Families of persons with severe psychiatric disorders	Family	SST for basic communication skills and PS to help families solve problems and achieve goals
Fisher and Carstensen (1990)	Elderly nursing home residents	Group	SST to improve conversational and other social skills in elderly persons
Heimberg et al. (1990)	Socially anxious clients	Group	Exposure to social situations, cognitive restructuring, and SST for peer intentions
Jacobson and Margolin (1979)	Maritally distressed couples	Couples	SST for communication skills and PS to address problem areas
Kelly (1995)	Persons with high HIV risk behavior	Group	SST to reduce HIV risk behaviors
Kleiner, Marshall, and Spevack (1987)	Agoraphobics	Individual	PS and exposure to feared situations
Liberman et al. (1989) Bellack et al. (1997)	Clients with schizophrenia	Group (can be adapted for individuals)	SST for communication skills, resolving conflicts, making friends, dealing with care providers, recreational and leisure activities
Linehan (1993)	Borderline personality disorder clients	Group and individual	SST and PS to address interpersonal skills, emotion regulation, and distress tolerance
Maiuro (1991)	Domestically violent men	Group	PS to reduce domestic violence
Monti et al. (1989)	Alcoholics	Group	SST for conversational skills, expressing feelings, dealing with alcohol-related situations
Mynors-Wallis, Davies, Gray, Barbour, and Gatz (1997)	Primary care clients	Individual	PS to address anxiety and depression problems interfering with functioning
Nezu, Nezu, and Perri (1989)	Persons with major depression	Individual	PS to address interpersonal problems and goals related to depression
Novaco(1975)	Persons with anger problems	Individual	Stress management skills, PS to identify suitable alternatives in conflict situations, SST for dealing with provoking situations
Salkovskis, Atha, and Storer (1990)	Suicidal persons	Individual	PS to identify problems and arrive at solutions that are alternatives to self-injurious behaviors
Valenti-Hein and Mueser (1990)	Mentally retarded adults	Group	SST and PS to develop dating skills (e.g., conversational skills, asking for a date, resisting persuasion)
Waldo, Roath, Levine, and Freedman (1987)	Mothers with schizophrenia	Group	SST to teach parenting skills
Wong and Woolsey (1989)	Chronic psychotic inpatients	Individual	SST to re-establish conversational skills in severely impaired clients

[a] SST = social skills training; PS = Problem solving training.

interviewing, managing interactions with supervisors, and peer relationships (e.g., Hughes & Rusch, 1989; Mueser, Foy, & Carter, 1986), and dealing with social situations involving alcohol and drug abuse (e.g., Hawkins, Catalano, Gillmore, & Wells, 1989). Thus, social and problem solving skills training are most often combined with other therapeutic modalities when used in the treatment of psychiatric syndromes or disorders, whereas skills training can be used on its own when the goals are to improve specific areas of functioning related to specific types of social situations.

6.08.7 SUMMARY AND CONCLUSIONS

Over the past several decades, social skills and problem solving training have become some of the most widely practiced interventions for the treatment of psychological disorders in adults. Therapies designed to improve social and problem solving skills are based on the assumptions that clients are capable of learning more adaptive interpersonal and self-management skills, and that these skills are most effectively taught in a systematic fashion, employing the principles of social learning theory. Training in social and problem solving skills can be conducted in a variety of different formats, such as with individuals, groups, couples, or families. Skills training approaches have enjoyed success across a broad range of clinical problems, including depression, poor social functioning in schizophrenia, social anxiety, anger, marital distress, and families coping with severe psychiatric disorders. Expertise in teaching social and problem solving skills is an important tool for clinical psychologists' armamentarium of treatment techniques.

6.09.1 INTRODUCTION

Heightened arousal, elevated somatic tension, increases in anxiety and worry, are common consequences of many everyday life experiences, and are also frequently associated with more serious mental health problems such as panic, obsessional disorders, and psychosis. It is not surprising, therefore, that some of the earliest proposed psychological treatments (e.g., Jacobson, 1938), have targeted arousal reduction. Indeed, many of these techniques (e.g., meditation, hypnosis) have their origins in nonscientific or religious practices and customs. Because of this, relaxation, biofeedback, meditation, and hypnosis are frequently regarded, particularly within the USA, as alternative or complementary therapies within medicine and are provided by specialist practitioners such as stress counsellors, hypnotherapists, and biofeedback practitioners. A recent review of "unconventional medicine" practised within the USA (Eisenberg et al., 1993) revealed, by means of a telephone survey of 1539 adults, that one in three respondents reported using at least one unconventional therapy in the past year, and a third of these had engaged in an average of 19 visits to a practitioner. Extrapolating from this pattern of contact to the entire population, the authors concluded that the extent of usage of unconventional therapies exceeded the number of primary care consultations and the economic cost ($13.7 billion) was comparable to out-of-pocket expenditure for all hospitalizations within the USA. Relaxation (13%), chiropracty (10%), and massage (7%) accounted for the most frequently used therapies, and back problems (36%), anxiety (28%), headaches (27%), chronic pain (26%), and cancer (24%) represented the most common health problems for which people had sought unconventional therapies. Although reliance on a telephone survey may have overestimated the prevalence of these techniques, Eisenberg et al. (1993, p. 251) conclude that these therapies have "an enormous presence in the US health care system." They further concluded that they represent a sizeable expenditure in healthcare, are used largely as adjuncts to conventional medical interventions, and are commonly undertaken independently of consultation with the medical practitioner responsible for conventional treatment of the presenting problem.

The above review included a wide range of treatments unrelated to the focus of this particular chapter. Nevertheless, relaxation (13%), imagery (4%), biofeedback (1%), and hypnosis (1%) were reported as being widely used within a 12-month period for a range of psychological problems (e.g. anxiety, depression, insomnia, and headache) which are frequently referred to a clinical or health psychologist, and this raises a number of intriguing questions. For example, what is the efficacy of these techniques, how severe are the problems for which these therapies are commonly employed, how effectively are these therapies delivered, what training and levels of competence are associated with the practitioners responsible for delivery of these therapies, and what proportion of therapists identified within Eisenberg et al.'s survey are clinical psychologists? Many of these questions go far beyond the scope of this chapter, since it is our intention to focus only on those specific therapies that are delivered as part of a formally constructed and scientifically evaluated package of psychological treatment. Nevertheless, clinical psychologists have to be aware of a wider context, whereby clients and their referral sources already have access to and are familiar with these treatments, and which goes far beyond that formally delivered within a clinic setting. It is likely, therefore, that such experiences may well influence how the efficacy and appropriateness of many of these therapies are judged, irrespective of any formal scientific evaluation of their effectiveness.

The major aims of this chapter, therefore, are to overview therapeutic techniques directed at modifying arousal and inducing relaxation. The therapeutic rationales underlying these techniques will be critically examined, together with an evaluation of their efficacy. The review will restrict itself primarily to adults and to problems broadly conceived as being associated with mental health. Some reference, however, will be made to physical health and behavioral medicine when reviewing more contemporary applications. We will conclude by attempting to appraise whether any common process or mechanism might underlie change brought about by the application of these diverse psychological treatments.

6.09.2 A THEORETICAL OVERVIEW OF AROUSAL DYSFUNCTION AND AROUSAL MODIFICATION INTERVENTIONS

A fundamental assumption that underlies this chapter is that elevated "arousal" is associated with a variety of mental and physical health problems, and that treatment methods targeted at "arousal" reduction will alleviate the severity of these conditions. Before we review these proposed treatments, it is important that this assumption is examined further. The critical questions are: what is arousal, what associations exist between elevated arousal and physical and mental health problems, what techniques exist to modulate arousal, and what are the mechanisms that mediate therapeutic change?

6.09.2.1 Arousal as a Hypothetical Construct

The construct of arousal has been revisited extensively within the literature, with respect to psychophysiology (Andreassi, 1989; Cacioppo

& Tassinary, 1990; Gale & Eysenck, 1992), emotion (Tucker, Vannatta, & Rothlind, 1990; Wagner, 1988), and clinical applications (Cacioppo, Berntson, & Anderson, 1991; Lader, 1975; Turpin, 1989, 1990; Wieisse, Davidson, & Baum, 1989). A variety of different arousal constructs can be identified, including arousal as central nervous system activation underlying an "arousal–sleep" continuum (e.g. Duffy, 1951), arousal as a general drive system affecting behavior as characterized by the inverted U model (e.g. Andrew, 1974; Claridge, 1987), and arousal as a psychophysiological construct identified by peripheral physiological response patterning (e.g., Lacey, 1967).

Despite the almost ubiquitous presence of the "arousal construct" within psychophysiology, its current usage has markedly declined. Its demise can be traced to Lacey's classic critique (Lacey, 1967) wherein the unitary nature of a physiologically mediated arousal drive, as advocated by Duffy (1951), was discarded because different autonomic response measures, behaviors, and situational factors were found to be dissociable. More recent psychophysiological studies have also failed to demonstrate a unitary arousal construct and largely support Lacey's original position (Venables, 1984). Peripheral autonomic measures of arousal, therefore, fail to demonstrate high intercorrelations, and instead display response patterns specifically determined by either individual differences or situational factors. More recent arousal theories have also discarded the notion of "arousal" as an unitary construct, but instead have stressed the complexities of stimulus—response relationships, different arousal systems, motivational systems, and neurophysiological or neurochemical substrates (Turpin, 1989).

Given the paucity of evidence to support a unitary arousal construct, it is perhaps paradoxical that the construct of arousal continues to receive widespread support as an explanatory construct within clinical psychology. This is, perhaps, best characterized by Gale and Eysenck's (1992) quote from Claridge (1987, p. 134): "I have often felt that as an explanatory concept in psychology "arousal" has many of the qualities of a difficult but persuasive lover, whom reason tells one to abandon yet who continues to satisfy an inescapable need." The question arises, therefore, as to why, particularly within the clinical arena, this irrational infatuation should continue. One answer is that "arousal" is best viewed as a hypothetical construct and, as such, it is difficult to define precisely or to operationalize. However, clinical psychology deals with many such similar constructs including, for example, "affect," "emotion," and "anxiety," and would be severely limited without the explanatory power that such constructs bestow on clinical formulations and conditions. Indeed, we suggest that arousal has important clinical utility and that its use can be progressed by treating it in a similar fashion to other clinical constructs such as anxiety. Just as anxiety is best conceptualized according to Lang's three-system model (Lang, 1968; Turpin, 1991), arousal might be broken down into three component systems: physiological, cognitive, and behavioral (Schilling & Poppen, 1983). Physiological arousal components will include both central activation and autonomic responding; cognitive components might refer to both subjective experience and verbal report, together with attentional consequences in terms of vigilance and selective attention; and behavioral components would account for levels of activity, together with the integration and coordination of motor responding. It is suggested that these three systems are loosely coupled in a fashion similar to that described by Öhman (1987) for emotion (Figure 1). The failure to observe perfect coupling by measures either within or between component systems is essentially similar to the *de synchrony* concept commonly entertained for anxiety (Rachman & Hodgson, 1974; Turpin, 1991) and frequently encountered elsewhere within psychophysiology (Cacioppo & Tassinary, 1990; Öhman, 1992).

Several implications for therapy emerge if arousal is treated according to the systems identified in Figure 1. First, a comprehensive assessment of arousal will involve attempts to measure all three systems. Indeed, Poppen (1988) has written extensively about the multimodal assessment of arousal and the outcome of relaxation training. He suggests the use of self-report relaxation and symptom scales, specific physiological measures (e.g., electrodermal, cardiovascular, electromyogram [EMG], skin temperature, and electroencephalogram [EEG] changes), and direct behavioral observations (e.g., Behavioral Relaxation Scale). Second, it becomes evident how overarousal might lead to dysfunction and the expression of a variety of symptoms including subjective distress, hypervigiliance and heightened attention, selective appraisal, hyperactivity, disorganized behavior, and autonomic and somatic overreactivity. The presence of such symptoms within a fear situation is consistent with the constructs of anxiety or panic. Finally, the three-system approach suggests a diversity of potential interventions that might moderate the expression of hyperarousal. The choice between a unitary model of arousal reduction and relaxation, on the one hand, and a multicomponent

model with a variety of specific treatment effects, on the other, is discussed later in this section.

6.09.2.2 Arousal Dysfunction and Health

Despite the difficulties described earlier in defining and measuring arousal, the construct has been used widely in association with etiologic theories of both physical and mental illness. Perhaps the most ubiquitous approach concerns diathesis–stress models of psychophysiological disorders (Gatchel, 1993). In particular, Sternbach (1966) postulated that situationally specific patterns of psychophysiological responding, if not adequately modulated by individual homeostatic mechanisms, would lead to dysfunctional patterns of physiological activation characteristic of so-called "psychosomatic disorders." Indeed, a diversity of theoretical models has been postulated in which elevated physiological arousal is included as a component of "stress" and is linked to both predisposition and the subsequent expression of a variety of physical health problems including headache, gastrointestinal disorders, hypertension, and asthma (McEwen & Stellar,1993; Steptoe, 1991; Weiner, 1977; Wiebe & Williams, 1992). Such models either incorporate physiological arousal as a component of an undifferentiated stress response (Seyle, 1950), or identify specific pathways associated with autonomic hyperreactivity and end-organ dysfunction, as exemplified by Freedman's hypothesized adrenergic mechanism implicated in Raynaud's disorder (Freedman, 1989). Although psychosomatic disorders are covered elsewhere, they represent a major area of study that relies on "stress–arousal" explanations of disease, and hence provide explicit therapeutic rationales for arousal reduction interventions (Lehrer, Carr, Sargunaraj, & Woolfolk, 1993). Nevertheless, as with arousal, many have argued that the concept of "stress" is too ill-defined and lacks specificity when defining individual mechanisms underlying disease or dysfunction (Steptoe, 1980).

A similar approach has been taken with regard to mental health, whereby stress is seen as a potential threat to mental well-being, and physiological stress or arousal is seen as a frequent consequence of psychosocial stressors and is manifested in a variety of psychological problems (Turpin & Lader, 1986). Such models underpin stress management approaches to mental health and the promotion of more adaptive life-styles, together with the development of more appropriate coping and adaptive responses to challenging stresses and life strain. Generic stress management approaches (Meichenbaum, 1993) are widely used for both physical and mental health problems, and are frequently employed within occupational and vocational settings (Reynolds & Shapiro, 1991).

Within the area of mental health, several specific rationales can be identified that link elevated arousal manifested across physiological, cognitive, and behavioral response modes with psychological dysfunction. Several psychological disorders are defined with particular reference to elevated levels of physiological arousal, which are situationally inappropriate and are frequently present in association with other aspects of overarousal, such as heightened attention and vigilance, somatic tension, and behavioral hyperactivity. Generally, arousal is treated nonspecifically and, for example, can be considered as a component of anxiety or even sleep dysfunction in the form of insomnia. With reference to anxiety, the three-system conceptualization of anxiety (Lang, 1968; Kozak & Miller, 1982; Turpin, 1991) is still the prevalent conceptual model, particularly when used as the basis for the evaluation of cognitive behavioral therapies. Physiological, behavioral, and cognitive components of anxiety and their manifestations can easily incorporate the arousal construct, and may even be reformulated whereby arousal is seen as an energetic or drive component of situational fear or anxiety. Similarly, insomnia is frequently (Borkovec, 1979; Nicassio & Buchanan, 1981) conceptualized as arising from both elevated physiological arousal and cognitive activation such as preoccupation. We will return in more detail to the three-system analysis of anxiety and arousal when specific therapeutic processes are discussed in later sections of this chapter.

Specific arousal components can also be identified for other psychological problems. For example, many sexual disorders are associated with specific patterns of arousal responding in the form of nonspecific physiological arousal, together with abnormal sexual dysfunction. Conditions such as vagismus, erectile dysfunction, and paraphelia might all be considered as involving a specific sexual arousal dysfunction. Similarly, heightened arousal is an important component of the expression of aggression and hostility, and may be specifically associated with particular patterns of cardiovascular and neuroendocrine response. Accordingly, it is frequently the focus of treatments aimed at anger management. Another disorder that might also be considered to include a specific arousal component concerns post-traumatic stress disorder, in which heightened anxiety, tension, hypervigiliance, and exaggerated startle responses are symptomatic features.

Finally, the construct of arousal has been used as a mediational variable for several other psychological disorders. Although physiological arousal may not necessarily be an essential component of the expression of the disorder, it is hypothesized that an underlying arousal dysfunction is instrumental in the expression of the disorder. For example, the consequences of arousal on the habituation and conditioning of fear responses has been implicated both in theories of phobic fear (Lader & Mathews, 1970) and in treatment through desensitization (Wolpe, 1982). Habituation is also suggested as an essential component of anxiety reduction within *in vivo* exposure treatments of anxiety disorders (Foa & Kozak, 1986) and also in the response prevention treatment of obsessive-compulsive disorder (Mills & Salkovskis, 1988). Elevated physiological arousal has also been suggested as a substrate underlying suggested psychomotor disorders such as torticollis (Meares, 1973), tics (Corbett & Turpin, 1985), and writer's cramp (Cottraux, Juenet, & Collet, 1983). More recently, arousal dysfunction has been implicated in relapse for psychosis, whereby arousal is seen as a mediating pathway in the stress–vulnerability model of schizophrenia (Nuetcherlein & Dawson, 1984; Tarrier and Turpin, 1992). Therapeutic approaches that have sought to modify the stress–vulnerability relationship, such as coping enhancement strategies (Barrowclough & Tarrier, 1992), frequently include arousal modulation techniques and rationales.

In summary, a variety of theoretical models exist that relate arousal dysfunction to the expression of physical and mental health problems. These frameworks, therefore, provide therapeutic rationales for arousal modification methods, assuming that such methods exist and can be shown to be efficacious. It is worth noting the wide range of problems that have been associated with an arousal dysfunction, and this perhaps lends greater credence to Eisenberg et al.'s survey that indicated widespread use of "unconventional" therapies for a wide range of conditions. In the next section the theoretical rationale underlying the treatment methods claimed to reduce arousal is reviewed.

6.09.2.3 Theoretical Basis of Arousal Modification Methods

Various psychological interventions have been suggested to reduce the level of elevated arousal (Lehrer & Woolfolk, 1993). The rationale for their use depends on how elevated arousal and the mechanisms underlying it are conceptualized. As seen in the previous section, arousal can be defined in a variety of ways—physiological, behavioral, and cognitive—and each mode can be measured and assessed independently. Moreover, it is likely that elevated arousal is the product of several distinct processes that may or may not be interrelated (see Figure 1). Accordingly, different arousal modification methods might be targeted at different components and rely on different mediational processes.

For example, a cognitive arousal component consisting of hypervigilance and appraisal of threat might be ameliorated either by cognitive therapy directed at the beliefs maintaining the negative appraisal or by the reduction and substitution of the prevalence of negative thoughts or worries *per se* using a cognitive distraction technique, perhaps involving meditation or imagery. A further reduction in a cognitive arousal component might also arise as a consequence of applied relaxation training directed at reducing physiological arousal, thereby eliminating a cue associated with interoceptive sensations of overarousal. Conversely, elevated somatic arousal, as induced by, for example, increased muscle tension and accompanying headache, might be reduced specifically by EMG biofeedback and training directed at the muscle group concerned. An emphasis on different arousal components, therefore, gives rise to what Poppen (1988) describes as multimodal theories of relaxation induction. Such theories originated from dualistic accounts of arousal reduction, which emphasized both cognitive and somatic relaxation (Davidson & Schwartz, 1976; Heide & Borkovec, 1983; Lehrer, Woolfolk, Rooney, McCann, & Carrington, 1983). The implications of these approaches are that the arousal requires assessing across a range of different domains, and that different aspects of arousal reduction methods might target different sources of arousal.

The above approach can be contrasted with unitary theories of arousal and relaxation induction, as exemplified by Benson's (1975) relaxation response. Many arousal reduction techniques are designed to induce a state of relaxation, which is conceived of as being antithetical to either arousal or stress and is typified as subjective calmness, lowered muscle tension, and lowered levels of physiological arousal. Indeed, many authors refer to the relaxation response in a similar, but opposite, fashion, to Selye's (1950) stress response. Moreover, several theoretical models have even implicated specific physiological mechanisms, particularly those related to autonomic balance, as mediating the relaxation state (Gellhorn, 1958). The rationale for some arousal reduction methods, therefore, is to lower arousal by the induction of an opposite and incompatible state of relaxation. This distinction between theories of arousal modulation, which rely on specific pathways, as opposed to a unitary model of relaxation induction is important when evaluating the differential efficacy of these techniques. If relaxation provides a common pathway, it may be that all arousal reduction interventions are equivalent in terms of process, and lead to identical outcomes, albeit with differing degrees of effectiveness in how easily achievable these outcomes are. Alternatively, if arousal reduction or relaxation induction is conceived of as a variety of specific components, different techniques might have differing degrees of efficacy expressed in different modalities for different individuals and disorders.

Indeed, the issue of specificity concerning a variety of relaxation methods has been emphasized by Lehrer and colleagues (Lehrer, 1996; Lehrer, Carr, Sargunaraj, & Woolfolk, 1994; Lehrer & Woolfolk, 1993). In contrast to Benson's (1975) unitary relaxation response, they propose an extension of Davidson and Schwartz's (1976) model, in which relaxation is viewed as a multicomponent process (of up to 12 separate components), and that specific techniques give rise to specific effects. For example, they suggest that cognitive changes might be expected from cognitive oriented methods such as meditation; somatic tension changes would be brought about by muscle-oriented methods, such as Jacobson's (1938) progressive muscle relaxation (PMR) or EMG biofeedback; and autonomic changes would be brought about by either electrodermal/thermal biofeedback or autogenic training. It should also be acknowledged, however, that specific effects may actually overlie a more generalized induction of a relaxation response, and hence these two approaches are not necessarily seen as mutually incompatible. Moreover, it is by no means conclusive as to how different interventions should be classified using multicomponent models. Autogenic training, for example, can be said to be directed at both autonomic and cognitive components. Similarly, hypnosis can also be considered as multimodal.

Lehrer and Woolfolk have tried to resolve the question of unitary vs. multicomponent models of relaxation by comparing the effects of different relaxation procedures on a range of outcome measures chosen to reflect the component processes described by Davidson and Schwartz (1976). This has been attempted either using a comparative treatment approach reviewing the results from different outcome studies (e.g. Lehrer et al., 1994) or by performing essentially analogue laboratory studies in which the effects of these different relaxation techniques on a battery of psychological and physiological measures are contrasted (Lehrer et al., 1983).

Generally, these studies are consistent with the view that the effects of different relaxation techniques are mediated by specific changes in somatic and cognitive arousal. Reviews, principally by Lehrer and Woolfolk (Lehrer 1996; Lehrer et al., 1994; Lehrer & Woolfolk, 1993; Lehrer et al., 1983), concerning the specific effects of relaxation techniques on physiological activity support the contention that muscle relaxation training, either in its original form as PMR (Jacobson, 1938) or in its modified form as abbreviated progressive relaxation (APR) (Bernstein & Carlson, 1993), produces significant decreases in muscle tension as measured by EMG. Similarly, EMG biofeedback, either delivered alone or in conjunction with modified PMR, has been shown to produce significant decreases in target EMG levels. However, whether the effects produced by EMG biofeedback delivered to a single muscle site can be generalized to other EMG sites is debatable (Alexander, 1975). Similarly, the data remain equivocal as to the comparative effectiveness of PMR, APR and EMG biofeedback on reducing EMG levels (Lehrer et al., 1994; Lehrer & Woolfolk, 1993) although, EMG biofeedback is probably superior to APR with regard to EMG reduction (Lehrer et al., 1994).

Nevertheless, the therapeutic rationale for muscle relaxation training does not restrict itself solely to reductions in muscle tension and EMG. Jacobson and his followers (see McGuigan, 1993) stressed that proprioceptive feedback from the musculature directly affects peripheral autonomic activity via the sympathetic and parasympathetic nervous system. This mechanism is based on Gellhorn's theories linking emotional experience to the skeletal musculature (Gellhorn, 1958; Gellhorn & Kiely, 1972). Accordingly, studies of relaxation training that include autonomic measures have generally demonstrated additional effects of, for example, lowered heart rate and electrodermal levels (Lehrer et al., 1994). Indeed, several studies have attempted to assess relaxation effects on the adrenergic system (see Freedman, 1994), and have included measures of peripheral muscle sympathetic nerve activity, blood norepinephrine levels (Hjemdahl et al., 1989), and platelet monoamine oxidase activity (Mathew et al., 1981). Other studies have also suggested effects on the immune system in the form of, for example, changes in killer cell activity and lymphocyte density (Gruber et al., 1993). Other arousal reduction methods have also been demonstrated to yield specific physiological effects. For example, breathing regulation techniques have been shown to lower physiological arousal and to normalize the EEG (Fried, 1993; Lehrer & Woolfolk, 1993).

The physiological effects of more cognitively mediated procedures such as autogenics and meditation have also been reviewed by Lehrer and colleagues (Lehrer et al., 1994; Lehrer & Woolfolk, 1993). Although the specific effects model of Davidson and Schwartz would predict greater cognitive than physiological effects for interventions such as meditation, Lehrer et al. conclude that the differential effects of meditation vs. relaxation training are equivocal. With respect to autogenic training, Linden (1990) cites a collection of studies demonstrating physiological effects of autogenic training, which support the relationship between subjective somatic sensations and physiological change, particularly in relation to changes in breathing and peripheral skin temperature.

Although the above studies generally substantiate the fact that the intended effects of relaxation on the levels of physiological activity are observed within treatment sessions, findings regarding the longer term effects of relaxation on physiological functioning are few. Indeed, a recent appraisal of the area which has been most thoroughly examined, that is, stress management and hypertension, reveals that a cautious approach to extrapolating from short-term effects to long-term outcomes might be warranted. Although relaxation-based stress management protocols revealed significant falls in blood pressure within hypertensive subjects (Patel et al., 1985), recent meta-analyses of studies within this area have produced less-promising findings (Jacob, Chesney, William, Ding, & Shapiro, 1991; Johnston, 1994; but see also Linden & Chambers, 1994; Linden, Stossel, & Maurice, 1996). Some of the factors responsible for these disparate findings probably include pre-existing levels of hypertension, subject selection and entry to the study, habituation and initial testing effects on blood pressure measurement, and failure of blood pressure reductions to generalize to everyday life situations (Jacob et al., 1991). It remains to be seen, therefore, whether the long-term effects of relaxation on elevated physiological arousal can be demonstrated, particularly if the methodological rigors adopted within hypertension research were to be more generally applied.

Most of the evidence reviewed in this section was derived from short-term treatment or laboratory analogue studies, and as such emphasizes process-related changes in relaxation measures. Whether these changes are also directly related to stable therapeutic outcomes with regard to reduction in symptoms and increased functioning remains to be demonstrated. Moreover, this assumes that the fundamental process underlying therapeutic change is physiological arousal reduction. However, this assumption has recently been challenged by Smith (1988, 1989), who has proposed that the therapeutic changes brought about by relaxation techniques are best explained by cognitive-behavioral formulations, as opposed to changes in physiological functioning. Hence changes in attitudes towards relaxation and stress, together with specific changes in personal cognitive schema, underlie therapeutic improvement, which may or may not be accompanied by a lowering of physiological arousal. The issue of specificity of effect will be examined in greater detail in the final section of this chapter.

6.09.2.4 Summary

In summary, arousal reduction methods are based on a variety of different explanatory therapeutic models. Indeed, the construct of arousal has been difficult to define and cannot be satisfactorily operationalized. Nevertheless, despite the construct being less frequently employed within experimental psychology, its use as an explanatory factor in clinical psychology continues to be prevalent. Many physical and mental disorders can be considered to involve an element of arousal dysfunction, either resulting directly in the expression of symptoms or indirectly as a result of some mediational role of arousal in triggering specific symptoms. Accordingly, a variety of therapeutic techniques targeted at arousal reduction have been devised in order to alleviate the effects of overarousal.

A variety of mechanisms have been proposed to underlie these techniques, ranging from the unitary induction of a relaxation response through to specific processes responsible for therapeutic change across different arousal components. It would appear that the majority of relaxation techniques produce some measurable effects on a variety of cognitive, somatic, autonomic, and central measures. However, the effects produced by different techniques do not appear to be equivalent, as might be predicted by a unitary theory such as Benson's. Nevertheless, there would appear to be evidence of some more generalized physiological effects of relaxation on autonomic, neurohumoral, and immune system functioning that underlie specific treatment-induced changes. Moreover, it should be acknowledged that some specific predictions of the multicomponent models have not been supported.

6.09.3 AROUSAL REDUCTION METHODS: GENERAL PROCEDURES AND SPECIFIC TECHNIQUES

In this section we systematically review clinical interventions derived in order to reduce arousal and facilitate positive functioning and therapeutic change. Only those techniques that are supported by a clear therapeutic rationale and that have been scientifically evaluated in terms of their efficacy are included. In addition, the review focuses primarily on mental health problems prevalent in adults. However, where appropriate, procedural modifications for child and elderly populations are noted. Physical conditions such as hypertension, headache, or pain control will not be systematically covered as these are reviewed elsewhere, but will be referred to if the studies are able to expand on some general procedural issues surrounding the implementation of these therapeutic techniques. The main techniques reviewed are relaxation methods, autogenic training, breathing modification, biofeedback, meditation, and hypnosis. However, many of these techniques have been advocated for use in a variety of different clinical problems based on a diverse range of therapeutic rationales. Hypnosis, for example, is claimed to be therapeutically beneficial in inducing a relaxation state, accessing "inaccessible memories and feelings," and promoting cognitive restructuring. Accordingly, we will restrict ourselves to covering only specific applications of these techniques where the therapeutic rationale upon which their use is based concerns the reduction or modification of arousal.

Before reviewing each technique in turn, we briefly describe and evaluate some general procedural factors. Contraindications and modification of the technique for specific problems or client groups will also be reviewed. The comparative efficacy of different techniques and their use for specific conditions are dealt with in the final section of this chapter, together with a discussion of the therapeutic mechanisms that might underlie their efficacy.

6.09.3.1 General Procedural Issues

The limited scope of this chapter prevents a detailed account of the clinical protocols used to deliver these methods. Instead, we aim to deal with some general procedural issues common to most relaxation or arousal reduction techniques, followed by a brief description of the essential features of each technique. Several excellent practical guides and training manuals have been published (Howell & Whitehead, 1989; Payne, 1995; Whitehead & Adams, 1991) and these should be consulted by the novice practitioner alongside this chapter.

6.09.3.1.1 Assessment

The successful application of relaxation techniques will depend on sound assessment and formulation of the clinical problem, leading to an appropriate rationale for their use. Assessment should focus on identifying the clinical problems amenable to relaxation techniques (Lehrer & Woolfolk, 1993; Poppen, 1988), together with establishing the presence of elevated physiological arousal, and self-reports or inferred observations of tension, anxiety, or worry (Crist, Rickard, Prentice-Dunn, & Barker, 1989; Poppen, 1988; Smith, 1989).

As discussed in Section 6.09.2.2, specific health problems said to be associated with elevations in arousal are generally identified as anxiety disorders (e.g., generalized anxiety disorder, panic disorder, and specific phobias), psychosomatic complaints (e.g., hypertension, tension headache, migraine, and asthma), elevated tension or somatic arousal (e.g., chronic pain, insomnia, and skeletomuscular disorders), and palliative problems and applications (e.g., side effects of chemotherapy). The purpose of assessment, therefore, is to substantiate the presence of any of these clinical indications, and to provide sufficient information to arrive at an individual formulation of the presenting problems. Such a formulation should address the rationale for the adoption of a relaxation-based intervention and should also rule out other more appropriate treatment approaches. The latter might concern the use of physically based medical treatments or more psychotherapeutically based interventions. Not that these treatments are necessarily mutually exclusive; in the case of psychological interventions in particular, relaxation techniques may well be used in conjunction with other cognitive and behavioral approaches. A final purpose of assessment should be to identify contraindications of applying relaxation-based therapies (see Section 6.09.3.2.1).

In order to formulate the presence of an arousal-related health problem that might be amenable to relaxation, it is important to verify the presence of elevated arousal either directly through physiological measurement or by inference from observation or self-report. Indeed, given the multidimensional nature of the arousal construct (see Figure 1), it is likely that individual measures will not be interchangeable and that a multicomponent approach to assessment will be required. Physiological measures of arousal will require sophisticated equipment and expertise, which is unlikely to be available in most clinical settings, but may well be available if biofeedback techniques are also on offer within the clinic. Simple assessments of elevated EMG or heart rate may also be accomplished using inexpensive commercially available monitors. Further advice and information on psychophysiological assessment procedures are available elsewhere (e.g., Cacioppo & Tassinary, 1990; Turpin, 1989).

An alternative to direct measurement is the use of either therapist observational checklists or client self-report instruments. The most widely used observational scale is the behavioral relaxation scale (BRS) (Schilling & Poppen, 1983), which is discussed in great detail in Poppen's instructional text (Poppen, 1988). A wide range of self-report scales is available to assess, for example, anxiety and worry, somatic arousal, stress and tension, state of relaxation and calmness. The use of these scales has been reviewed by Smith (1989).

6.09.3.1.2 Therapeutic rationale

Assuming that assessment has revealed a need for relaxation training, and the most appropriate method has been chosen for the individual, a common feature of most methods is to present a clear therapeutic rationale to the client (Bernstein & Carlson, 1993). This will usually involve an explanation or reformulation of the client's problem in terms of anxiety or an inability to relax, the provision of basic information on stress and anxiety, and an explanation of how relaxation can be induced and its potential benefits to the client. The latter will usually stress the importance of regular practice and emphasize that the client must take responsibility for his or her own therapy. It is important that at the beginning of therapy the client has an accurate expectation of the nature of the therapeutic intervention and his or her own commitment to the therapy. The adoption of a clear therapeutic rationale, therefore, together with agreed therapeutic goals between therapist and client cannot be overstated. At the very least it provides the therapeutic framework within which relaxation techniques can be learnt and practised. Indeed, some would argue (e.g., Smith, 1989) that the therapeutic benefits of relaxation are dependent on the client's reframing of the clinical problem cognitively, and arise as much from changes in cognitive schema and appraisal processes as they do from any accompanying changes in physiological arousal.

6.09.3.1.3 Practical considerations

In addition to introducing to the client an appropriate rationale, it is also important that the client is provided with instructions concerning environmental considerations for relaxation training. Important requirements are a comfortable chair and the adoption of a reclining position, avoiding extraneous noises or interruptions, subdued lighting and a comfortable ambient room temperature, and the wearing of loose clothing that does not restrict body movement. These factors apply both to clinic sessions and homework practice. Finally, the adoption by the therapist of a smooth, quiet, and almost monotonous voice for the presentation of instructions is also an important consideration.

6.09.3.1.4 Presentation of the technique

Different techniques clearly have to be delivered to the client by the therapist in many different ways. Nevertheless, certain choices regarding the mode of training have to be made. For example, what amount of information is provided prior to training (booklets, audiocassettes, videos, etc.)? The role of the therapist in providing within-session modeling of the techniques for the client, and the opportunity for the client to rehearse techniques before the therapist and to receive feedback are examples of procedural questions that have to be resolved. Similarly, the therapist has to decide between the use of individual sequences of exercises, whereby individual progression is based on mastering each stage and the strict adherence to a standardized and, possibly, inflexible protocol. The majority of published studies of relaxation training relate to individualized, one-to-one therapy as opposed to group delivery methods. However, in practice, many practical relaxation training programs are directed at group approaches (Howell & Whitehead, 1989; Whitehead & Adams, 1991). Other considerations include the number of sessions, homework practice, compliance, and follow-up and booster sessions. The overall impact of these factors on treatment efficacy are now reviewed.

6.09.3.1.5 Evaluation of procedural factors

Several of the above general procedural factors commonly found in most forms of relaxation training have been investigated in order to determine their influence on therapeutic outcomes. These have included taped vs. live instruction, the use of homework practice sessions, and brief vs. extended practice, and they have been the subject of several reviews (Bernstein & Carlson, 1993; Borkovec & Sides, 1979; Blanchard et al., 1991; Hillenberg & Collins, 1982; Lehrer & Woolfolk, 1993). Although none of these reviews yield unequivocal conclusions, several consistent recommendations emerge. First, live instructions, whereby the client is able to control the progress of training by moving systematically from one muscle group to the next, with access to appropriate observation of and feedback from the therapist, appears superior to the sole use of standard taped instructions. Second, most clinical trials have included home practice sessions, perhaps supplemented by taped instructions and measures of homework compliance. Some data exist to support the additional benefits of prolonged and regular homework practice, although some studies (Borkovec et al., 1987; Nelson & Borkovec, 1989) have failed to support such an effect. Compliance and overreporting of homework practice sessions might explain some of the inconsistencies in these studies (Bernstein & Carlson, 1993). Third, it would appear that the greater exposure to relaxation training, either through extended clinic sessions or through continued application outside of the clinic, is more likely to be associated with maintenance of therapeutic change. The continued application of brief relaxation procedures, as opposed to more extended periods of relaxation training, has been argued by Lake and Pingel (1988) to be an important determinant of outcome for headache patients. It should be emphasized, however, that the above recommendations are largely based on clinical guidelines rather than extensive outcome studies. Moreover, specific procedural recommendations for different techniques or subject groups have yet to be evolved.

6.09.3.2 Specific Techniques

The purpose of this section is to provide the reader with a brief account of the essential components of each technique. More detailed clinical protocols are available elsewhere (Lehrer & Woolfolk, 1993). As relaxation-based techniques have been the focus of this chapter so far, greater emphasis will be placed in this section on detailing the background to other techniques, such as biofeedback, meditation, and hypnosis, which have also been commonly employed as arousal reduction methods.

6.09.3.2.1 Relaxation-based methods

(i) Jacobson progressive muscle relaxation

The development and application of Jacobson's ideas have been reviewed extensively by McGuigan (1993). Jacobson's method was devised in 1938 and seeks to train subjects in the ability to perceive muscle tension accurately, to control and hence reduce tension, and to relax their muscles differentially. The training involves detailed familiarization with the majority of muscle groups and an emphasis on enhancing awareness of muscle tension. Discrimination training is brought about by the method of "diminishing tensions," whereby the client learns to effect and detect the smallest possible muscle contraction in a variety of different muscle groups. Once the skill of discrimination in muscle tension has been acquired, the client can then bring about "differential relaxation" of his or her muscles, which entails only contracting those specific muscles that are functionally required for action, and relaxing all other muscles unassociated with the ongoing physically active group. The distinctive feature of Jacobson's approach is its specific emphasis on muscle tension and control, and the absence of any cognitive or suggestive components directed at the induction of a subjective feeling of relaxation.

(ii) Abbreviated progressive muscle relaxation

Jacobson's techniques were adapted, notably by Wolpe (1958) and Paul (1966), and modified in the 1960s to form part of the basis for several behavioral treatments, including systematic desensitization. The major changes were a shift from actual to subjective tension, an abbreviated and standardized protocol, use of the tension-release cycle, and greater emphasis on subjective and cognitive approaches. Many of these changes were incorporated into a highly influential treatment manual produced by Bernstein and Borkovec (1973). The specific instructions underlying the technique involve the client performing a series of tension-release cycles in a systematic manner across 16 muscle groups, beginning with the hand and forearm, moving through the forehead, face and neck, down to the abdomen, and finishing with the feet. Each tension-release cycle involves the client contracting the specified muscle according to a cue "tense" or "now," holding and sensing the contraction for 5–7 seconds, and relaxing the muscle on the command "relax," followed by a period of 30–40 seconds during which the client focuses on the sensations of relaxation. A detailed account of these procedures is provided by Bernstein and Carlson (1993). Various modifications have also been proposed to the standard Abbreviated Progressive Relaxation Training (ABRT) protocol, including the establishment of relaxation cues in the form of cue-controlled relaxation (Grimm, 1980) and attempts to generalize the relaxation response into everyday settings, such as in applied relaxation training (Ost, 1987).

(iii) Breathing training

A variety of techniques exist to induce relaxation through the modification of breathing. Specific instructions to entrain diaphragmatic breathing have commonly been used as adjuncts to APR (Bacon & Poppen, 1985; Poppen, 1988) and have also been the focus of cue-controlled relaxation procedures (Grimm, 1980). For disorders such as panic, whereby sensations arising from hyperventilation have been implicated, controlled breathing exercises have been used effectively (Clark, Salkovskis, & Chalkley, 1985). More specific techniques involving respiratory feedback and slowly paced breathing have also been developed (Fried, 1993; Montgomery, 1994). Finally, breathing regulation is also a common component of yoga (Patel, 1993) and other meditation-based techniques (Carrington, 1993), and these are discussed later.

(iv) Autogenic training

Instead of focusing directly on muscle tension as a means to induce relaxation, autogenic training (AT) involves a set of exercises targeted at various physiological end-organs whereby a state of relaxation might be induced. These techniques have been described in detail by Linden (1990, 1993) and are based on the work of Schultz and further developed by Luther. "Autogenics", as a term, essentially means "self-exercise" or "self-induction" therapy and relies on a theoretical rationale whereby the client gains psychophysiological self-control of autonomic functioning and is able to achieve relaxation. Control is said to be gained by the client focusing on body sensations in a *passive* manner. This is achieved by the client *subvocally* repeating six standard formulas that are designed to induce physiological change: these include the "heaviness formula" directed at the muscles, the "warmth formula" aimed at peripheral blood flow, the "heart formula" associated with the heart rate, and the "breathing formula" targeted at a natural breathing rhythm. Like many other relaxation techniques, AT has been modified and used in combination with other methods, particularly thermal biofeedback (Norris & Fahrion, 1993). Indeed, AT techniques and imagery are commonly employed to assist relaxation induction within a range of different procedures. However, it should be emphasized that the classical use of AT also implies a therapeutic rationale whereby the techniques facilitate cathartic experiences in the form of "autogenic discharges."

6.09.3.2.2 Biofeedback

Biofeedback is the regulation of autonomic nervous system functions, such as blood pressure, heart rate, and sweating, by the subject continually monitoring that function and being rewarded (usually simply by the knowledge of his or her success) for changing that activity in a desired direction. Feedback is usually conveyed either auditorily by the pitch of a continuous tone or by using a visual display.

The idea that a person, with training, can selectively influence the activity of a particular autonomic function, notably in the direction of diminished arousal, has been in existence for a long time and is traditionally associated with Eastern practices such as meditation and yoga. It has been claimed that practitioners of these forms of meditation have the ability to attenuate their vital functions (e.g. heart rate) to an extraordinary degree. In contrast, Western scientific interest in autonomic control has been a recent development and was stimulated by the work of Miller and his colleagues on the operant conditioning of autonomic responses in animals, particularly the curarized rat. This research was significant from a theoretical standpoint because the findings suggested that autonomic and visceral responses, hitherto held only to be amenable to alteration by classical conditioning, could be modified by positive reinforcement within an instrumental or operant-conditioning paradigm. Around that time also, interest had been shown (Kamiya, 1969) in the operant conditioning of the alpha EEG rhythm (as a means of achieving altered states of consciousness) and of changes in skin conductance (Shapiro, Crider, & Tursky, 1964) and heart rate (Engel & Hansen, 1966). However, these studies on humans were criticized by Katkin and Murray (1968) for their lack of controls for mediating responses such as breathing.

Despite the many problems encountered in replicating some of the above animal laboratory work, it proved very influential and a wide range of clinical applications have been investigated since then and have focused mainly on two types of problem. First, anxiety and stress disorders, where the aim of biofeedback is to reduce general arousal levels; and, second, disorders presenting as somatic problems (e.g., pain, tension headaches, and irritable bowel syndrome), which may be triggered or exacerbated by overarousal and where again the biofeedback is either aimed at general relaxation or is targeted more specifically to the affected organ or function in order to achieve self-regulation.

Biofeedback techniques associated with generalized arousal reduction have included from the outset alpha rhythm EEG feedback (Budzynski & Stoyva, 1973) and other methods such as electrodermal (skin conductance) feedback (usually from the hand) and surface EMG feedback, for example, from the frontalis muscle, or in combination. The latter techniques are now more commonly used and may also be employed to augment systematic *in vitro* or *in vivo* desensitization by enabling closer monitoring of the return-to-relaxation phase, and thereby assisting patients to achieve this (Stoyva & Budzynski, 1993).

Procedurally, treatment by biofeedback begins with an assessment of the patient's presenting problem and an explanation of the rationale of biofeedback. Initial training sessions with the therapist enable the patient to become more attuned to cognitions and bodily events that are associated with increase in arousal. This training has been reported to be productive in establishing anxiety-evoking cognitions in the case of generalized anxiety (Budzynski & Stoyva, 1973). This stage is followed by daily practice at home (multiple short sessions) until mastery of the target response has been achieved and the patient can be weaned off the biofeedback device. Again, it should be noted that biofeedback is often combined in treatment with other self-relaxation methods, such as autogenic training or progressive relaxation (Lehrer et al., 1993).

6.09.3.2.3 Meditation

Shapiro (1982) defines meditation as referring to "a family of techniques which have in common a conscious attempt to focus attention in a non-analytical way and an attempt not to dwell on discursive, ruminating thought" (p. 268). However, he points out that this definition covers a wide variety of methods of meditation. Moreover, the methods may involve either a state of mental relaxation, or excitement and arousal; either physical restfulness or, as in the case of the whirling dervish or tai chi, physical activity; and different prescriptions as regards the distribution of attention (focus on awareness generally, focus on a specific thought, or a shifting form one to the other). In general, however, it is not the contents of awareness that are significant but the process of attending to the objects of one's awareness.

Such a definition of meditation presupposes no adherence to any cultic philosophy or beliefs, a point made by Carrington (1993) in her overview, citing transcendental meditation as the most widely known and extensively studied of the Western methods. Carrington goes on to distinguish two methods that have been used in clinical settings, namely clinically standardized meditation and the respiratory one method. In the former, the meditator selects a mantra (usually not a real word) which he or she initially repeats aloud with the instructor in the training phase. Later, the mantra becomes the focus for silent meditation, twice-daily for 20 minutes being recommended, although many meditators reduce the frequency of sessions to one per day or less after training (Carrington, 1993). Training is facilitated by written instructions and a cassette tape. The respiratory one method (Benson, 1975) requires the meditator to repeat silently the mantra (which may simply be the number one), pacing this with the outward breath. It is thus more structured, and is presumed to be more "effortful" than the above method (Carrington, 1993).

Meditation is recommended as an activity for everyday living, one which reduces the stress of daily life, encourages a calmer outlook, promotes greater self-awareness and inner contentment, and so on. However, it has also been used clinically in the case of anxiety (Kabat-Zinn et al., 1992; Kirsch & Henry, 1979; Thomas & Abbas, 1978), insomnia (Woolfolk, Carr-Kaffeshan, & McNulty, 1976), hypertension (Surut, Shapiro & Good, 1978), psoriasis (Gaston, 1988–1989), asthma (Honsberger & Wilson, 1973), and alcohol and drug abuse (Benson & Wallace, 1971; Parker, Gilbert, & Thoreson, 1978; Taub, Steiner, Weingarten, & Walton, 1994).

6.09.3.2.4 Hypnosis

The origins of hypnosis may be traced back to the ideas and practices of the Austrian physician Franz Anton Mesmer (1734–1815). However, so great has been the transformation since that time that mesmerism, on the one hand, and modern hypnosis, on the other, bear little resemblance to one another. Hypnosis as it is now practised may be operationally defined as

> an interaction between two people (or one person and a group) in which one of them, the hypnotist, by means of verbal communication, encourages the other, the subject or subjects, to disattend to their immediate realities and concerns and to focus their awareness on inner experiences such as thoughts, feelings and imagery. The hypnotist further attempts to create changes in the way subjects are feeling, thinking and behaving by directing them to imagine various events or situations which, were they to occur in reality, would evoke the intended changes in the subjects. (Heap, 1995, p. 649)

The state of inner focus (which is almost invariably, though not always, associated with feelings of calmness and physical relaxation) is what nowadays most practitioners appear to mean by a "trance." As such it is continuous with everyday experiences that are popularly given that label (e.g., absorption in a daydream). It is generally achieved by the hypnotist's use of suggestions and imagery, which denote feelings of calmness, heaviness, tiredness, sleepiness, and so on, a procedure known as "hypnotic induction." Whichever method is used, it may be learned by the patient and practised regularly at home, either by himself or herself or with the aid of a recorded tape. At its simplest then, "self-hypnosis" resembles meditation and other self-directed relaxation procedures such as progressive muscular relaxation and autogenic relaxation, and the general aims are similar (Sanders, 1993).

In the "heterohypnotic" context, having performed an induction procedure, the hypnotist proceeds to give suggestions to the patient that are intended to elicit the desired therapeutic changes. It is useful, however, to bear in mind that rather than a therapy in itself, hypnosis is best regarded as an adjunct to therapy (Gibson & Heap, 1991), and the range of problems to which it is applied almost matches that seen in any mental health context. Thus it may be used to augment a cognitive-behavioral approach to, say, anxiety management by the use of suggestions of calmness and symptom control in mentally rehearsed, anxiety-provoking situations, and posthypnotic suggestions (i.e. suggestions to take effect after the hypnotic session) of the immediate and effective use of self-control techniques in such situations. These procedures, which may be targeted at any of the autonomic, cognitive, or behavioral levels, may be augmented by the use of cues or "anchors." For example, a positive feeling may be coupled with a simple gesture such as the clenching of a fist (Stein, 1963); this technique may be rehearsed repeatedly in imagination, and the posthypnotic suggestion be given that this feeling may be re-evoked by the same action as and when required.

Another very common routine is that of "ego strengthening"; this consists of suggestions, usually delivered towards the end of a session of hypnosis, which are intended to promote self-confidence and more positive self-esteem. Use is often made in this procedure of symbolic and metaphorical imagery and guided fantasy (Stanton, 1990, 1991).

Hypnotic procedures are often used as an adjunct to dynamic psychotherapy, notably by the use of what are termed "exploratory" and "uncovering" techniques. These include age regression and various guided imagery techniques (Gibson & Heap, 1991; Karle, 1988), and are generally based on the notion that unconscious processes lie at the root of the patient's presenting problem. Nevertheless, these techniques may be put to good use by the eclectically minded cognitive or behavior therapist (Gibson & Heap, 1991; Heap, 1991).

One difference between hypnosis and other methods of arousal control is that the capacity to respond to hypnotic suggestions varies (around a central tendency) among the population, and is a relatively stable trait (Hilgard, 1991). Standard scales exist for measuring hypnotic susceptibility (or, as some would prefer, suggestibility) and these have good psychometric properties (for a useful overview see Fellows, 1988). However, because so many factors contribute to the outcome of therapy and because hypnosis tends to be used in an adjunctive manner, the relationship of hypnotic susceptibility to therapeutic outcome is highly variable and tends to be of modest proportions (Spinhoven, 1987; Wadden & Anderton, 1982).

6.09.3.3 Indications, Side Effects, and Contraindications

6.09.3.3.1 Client selection

The self-regulation methods presented here have the advantage that their immediate aim is to create pleasant experiences purely from something the patient does for him- or herself, and ultimately, at any time, control of treatment is in the hands of the patient, and may be instigated, directed and terminated at his or her own initiative. Consequently, patients require a certain level of autonomy and ability to manage their own daily activities, and perhaps a more "internal" locus of control (see the review by Lehrer & Woolfolk, 1993).

Adherence to a prescribed program of self-directed relaxation has been noted to be a problem by a number of authors (Bernstein & Carlson, 1993; Carrington 1977; Linden, 1993) and some studies have indicated overreporting of home-based practice by patients (Hoelscher, Lichtenstein, & Rosenthal, 1986). A problem that is more serious than simple lack of discipline on the patient's part (or inadequate instruction or direction on the therapist's part) may be that training in self-regulation does not satisfactorily address the patient's problems. There may also be issues relating to secondary gain or marital and family relationships, or unacknowledged or undisclosed areas of difficulty and anxiety that need to be the focus of a more extensive cognitive behavioral or psychodynamic intervention.

Another characteristic of potential relevance to patient selection is absorption, the tendency of an individual to become deeply immersed in the object of his or her attention (e.g., a book, some music, or a daydream). This quality may be measured using a standardized questionnaire (Tellegen & Atkinson, 1974). There is a modest relationship between absorption and measured hypnotic susceptibility (Council, Kirsch, & Hafner, 1986), and there is some evidence of a tendency for good meditators to be high on absorption (Davidson & Goleman, 1977).

Hypnotic susceptibility is itself related to outcome in several of these self-regulation methods, although only modestly so, and not at all in the case of biofeedback (Lehrer & Woolfolk, 1993; Sigman & Phillips, 1985). Whereas, as was stated earlier, practitioners may make use of self-regulation procedures in combination, biofeedback and hypnosis do not appear to complement one another in this way, and the net effect may be less positive than either technique used alone (Edmonds, 1979; Sigman, 1988). Dumas (1980) has suggested that different attentional processes may be involved in these two methods.

There is a case for favoring high susceptibility subjects as candidates for hypnotic self-regulation in, for example, an anxiety-management training program that relies heavily on suggestions of automatic responding (Spinhoven, 1987). There is also a case for offering hypnosis, and even simply explicitly calling the procedures "hypnosis," when it is the treatment requested by the patient, and not doing so when the patient has a negative attitude to hypnosis (Kirsch, 1996). Perhaps equivalent recommendations may be made in the case of the other methods.

6.09.3.3.2 Side effects and adverse reactions

Notwithstanding the relatively benign nature of the procedures under discussion, adverse effects have been noted in the literature, and precautions and contraindications have been detailed by various authors (e.g. Shapiro, 1982, for meditation; Bernstein & Borkovec, 1973, for progressive relaxation; Linden, 1993, for autogenic training; and Crawford, Hilgard, & Macdonald, 1982, for hypnosis). Reported effects, which are generally transient, include unwelcome and intrusive imagery, anxiety, panic, dizziness, confusion, restlessness, and headache. For example, Edinger and Jacobsen (1982) surveyed 116 clinicians who reported on the effects of relaxation training on 17 542 clients. The following prevalence of problems was reported: intrusive thoughts (15%), fear of losing control (9%), disturbed sensory experiences (4%), muscle cramps and spasms (4%), inappropriate sexual arousal (2%), and dissociation (0.4%). Other problems less frequently reported included laughing, coughing, and falling asleep.

Indeed, the presence of such side effects has led to the awareness of a particular problematic response known as "relaxation-induced anxiety (or panic)," which appears to represent a cumulative build-up of arousal during the relaxation procedure itself. Explanations have included fear of losing control, fear of the sensations of relaxation itself, "interoceptive conditioning" and brief bursts of hyperventilation (Adler, Craske, & Barlow, 1987; Bernstein & Borkovec, 1973; Borkovec, 1987; Braith, McCullough, & Bush, 1988; Ley, 1980).

These effects do not in themselves contraindicate the use of relaxation procedures in the individual so affected; exploration of the reasons for their occurrence, and adjustments to the procedure may be required. For example, within the pretreatment rationale it may be useful to acknowledge the existence of side effects, while emphasizing that their occurrence is usually infrequent. When side effects do occur, this is confirmation of the prior information provided and less likely to be interpreted in a catastrophic manner. The client should be assured that side effects are probably of a transitory nature and that, from a positive and constructive perspective, they indicate that the training is clearly having *some* effect. In this way the client is also engaged with the treatment. Adaptive strategies may include focusing on breathing in order to reduce the likelihood of hyperventilation, and the use of mantras such as "calm" and "relax." In the case of fear of loss of control, the use of a more individualized approach, self-paced by the client, should be considered. If problems persist, the therapist should consider adopting a different technique, preferably based on some formulation as to why the side effects are being experienced with the current relaxation method employed.

Finally, it should be recognized that the possible presence of unreported side effects might account for treatment noncompliance and rates of uptake and dropout within therapy. As will be discussed in greater detail in Section 6.09.4.2, relaxation-based treatments have compared favorably with more recently evolved cognitive-behavioral techniques, sometimes rather unexpectedly since they have frequently been included in therapy outcome studies as a control condition. However, there are strong indications that they may be less acceptable to clients, resulting in lower uptake and higher dropout rates in therapy. Such effects may be due to a variety of factors, such as treatment credibility and client expectations; however, negative side effects might also account for possible reduced acceptability.

6.09.3.3.3 Contraindications and procedural modifications

There is a limited literature regarding the suitability of arousal reduction techniques for specific clinical problems or client groups. Where contraindications have been recommended they tend to have been founded on clinical observation rather than on outcome data, and it is often uncertain whether specific warnings of adverse effects can be generalized across all methods. A brief overview of these issues is provided here, together with some possible procedural modifications for specific client groups that might result in making these techniques more appropriate.

The presence of clinical depression is an important factor to consider. Shapiro (1982), for example, suggests that meditation may not be appropriate for chronically depressed individuals, for whom a low level of arousal is more characteristic. Neither, the same author argues, is it pertinent to the needs of the socially withdrawn individual. Depression has also traditionally been said to contraindicate hypnosis (Burrows, 1980), one argument being that it can have mood-elevating properties that may provide the suicidally depressed patient with the impetus to take his or her own life. There is not, however, a great deal of evidence for this, and in recent years hypnosis has been used to augment cognitive-behavioral therapy of depression (Alladin & Heap, 1991). Lehrer et al. (1993)

have also reviewed whether stress management techniques in general, but particularly those involving relaxation training, should be directed at depression, since received clinical wisdom would counsel against such an approach. Again, they report that stress management is associated with improvements in depression, particularly when it is combined with other therapeutic approaches. Nevertheless, they only cautiously suggest the possible inclusion of stress management in programs for the treatment of depression in view of the problems of motivating clients to comply with an active homework-based therapeutic intervention, and the need to ensure that the most effective treatments are employed in the case of potentially suicidal clients. We may conclude that self-regulation may be used with the clinically depressed patient with due care, and as one component of a broader therapeutic program.

One adverse consequence of the methods in question seems to be, as in the case of depression, the amplification of an existing negative internal state. Individuals who lack well-developed reality-testing processes, such as psychotic and borderline patients, and indeed who may hallucinate, may be unsuitable candidates for self-regulation methods, at least without close supervision (Carrington, 1977; Gibson & Heap, 1991), and there is some evidence that prolonged meditation may precipitate psychotic episodes in some highly vulnerable individuals (Lazarus, 1976). Similarly, Adler and Morrisey-Adler (1983) have reported the possibility of increased hallucinations with biofeedback training. Nevertheless, Lehrer et al. (1993) have reviewed several studies purporting to report beneficial effects of stress management within psychosis. Given the contemporary interest in psychological management techniques for psychotic symptoms, it is perhaps time to reassess the application of these techniques to schizophrenia. Moreover, many of these recent approaches to the psychological management of psychotic symptoms are based on the stress–vulnerability model (Clements & Turpin, 1992; Tarrier & Turpin, 1992), which identifies increases in arousal as an underlying mechanism in the production of psychotic states. Further support for such an approach may also be derived from studies of clients' own self-control strategies for psychotic phenomena, which commonly include arousal reduction methods. Indeed, these have been capitalized on by Tarrier and Barrowclough's therapeutic approach known as self-control enhancement therapy. It remains to be seen, however, if these techniques are useful in both relieving psychotic symptoms as well as reducing excessive levels of anxiety in these clients.

There are some other conditions the presence of which warrants special consideration by the therapist. For example, Carrington (1993) advises careful monitoring of patients' medication requirements (antihypertensive and anxiolytic drugs), as these may alter during treatment. Stoyva and Budzynski (1993) give a similar warning for patients with insulin-dependent diabetes. Clearly, patients should not deny themselves their essential medication in the belief that otherwise they are failing in their self-regulation procedure (Gibson & Heap, 1991).

In addition to specific clinical problems that might mitigate against the use of arousal reduction techniques, the applicability of these techniques in general to certain client groups has been questioned. Essentially, there are two major considerations: do clients possess sufficient cognitive functions to benefit from such an approach, and are there any physical barriers that might prevent the implementation of relaxation or other related exercises? Client groups that might be considered unresponsive to a stress reduction approach because of cognitive or developmental limitations might include children, people with a learning disability, or individuals with acquired brain damage. Poppen (1988) specifically reviews the application of behavioral relaxation training with these populations, and provides examples of successful interventions. Similarly, Lehrer et al. (1993) have reviewed applications of stress management techniques specifically for children, and report positive findings in relation to hyperactivity and academically related anxiety problems.

Physical restrictions such as arthritis or neuromuscular dysfunction can give rise to serious obstacles to using muscle relaxation based methods with either brain-injured or elderly populations. Two different approaches might be used to overcome this problem. First, a variant of PMR has been designed that is based not on muscle contraction but on muscle stretch. It is argued by Kay and Carlson (1992) that this approach might be more acceptable to older adults. Second, it could be argued that more cognitively focused interventions might be of greater benefit to older adults who experience either restricted movement or arthritic pain. For example, Scogin, Richard, Keith, Wilson, and McElreath (1992) have demonstrated that imagination-based relaxation procedures were as effective as APR for an elderly population. Deberry, Davies, and Reinhard (1989) have also reported that a meditation based relaxation approach was more effective than a purely cognitive approach in dealing with emotional problems in an elderly group of clients.

6.09.4 COMPARATIVE OUTCOMES AND THERAPEUTIC MECHANISMS

In this final section we briefly address the issue of comparative outcomes for a variety of adult mental health problems, focusing particularly on anxiety disorders. In doing so, we draw attention to relationships between various techniques of arousal reduction and differential therapeutic responses across a range of outcome measures. We also speculate about possible therapeutic processes that might underlie these different relationships.

6.09.4.1 Overview of Outcomes

In Section 6.09.2.3 we discussed the evidence supporting the notion of treatment specificity across a range of arousal reduction methods. However, the majority of these studies focused on within-session changes and relied on either experimental or analog designs as opposed to clinical outcome studies employing patient samples. Moreover, the question that was addressed concerned the effectiveness of individual techniques in modifying various measures of arousal or stress. For example, if EMG biofeedback is compared to PMR, which method gives rise to the greatest change in arousal as measured by muscle tension, autonomic activity, and self-reported calmness? Although such studies lend credence to the validity of the proposed therapeutic mechanisms said to underlie these techniques, and although they support, to some degree, the treatment specificity hypothesis (see Lehrer & Woolfolk, 1984), they do not address the question of clinical efficacy for individual disorders. To achieve this, it is essential that studies include clinical samples that fulfil specified diagnostic criteria, that therapeutic change is assessed with respect to specific measures of psychological distress and functioning and not just arousal dysfunction, that suitable designs are employed to assess the contribution of nonspecific treatment effects, and that long-term follow-up assessments are also included.

Many reviews exist that focus on clinically relevant studies as described above. Some of these were discussed in Section 6.09.3.1 in relation to the effectiveness of different procedural components of relaxation techniques, such as homework compliance and taped instructions. Others have compared the general effectiveness of arousal reduction techniques in modifying psychological distress in patient samples. An early review by Glaister (1982) concluded that relaxation training leads to decreases in autonomic arousal both within and across sessions, and that these changes were associated with reductions in behavioral avoidance and distress. However, he suggested that the use of only relaxation is probably inferior to exposure treatments. Using a meta-analysis approach, Eppley, Abrams, and Shear (1989) compared the effects of different relaxation techniques on measures of trait anxiety. They concluded that transcendental meditation was superior to other techniques, and suggested that this might be related to the emphasis given to "effortless relaxation," the concentration of training sessions within the first few weeks, and the regularity and duration of practice. Expectancies and demand characteristics were said not to influence effect size. However, these conclusions should be treated cautiously, especially when generalizing to adult mental health populations, since studies involving psychiatric patients were excluded from these analyses, mainly because of the lack of application of transcendental meditation to this subject population. Similar narrative reviews have been published by Lehrer et al. (1994) and provide useful overviews of the comparative efficacy of relaxation techniques in relation to, for example, psychosomatic disorders, insomnia, anger management, and substance abuse.

Instead of focusing solely on arousal reduction techniques, more recent outcome studies have tended to address the comparative efficacy of a range of cognitive-behavioral interventions for specific disorders. This reflects the growth of psychotherapy outcome research for anxiety disorders and the continued inclusion of relaxation-based therapy components within these studies. However, it should be recognized that the rationale for the inclusion of arousal reduction methods has differed across individual studies. Some researchers, probably influenced by Mark's (1976) negative critique of the importance of relaxation in exposure treatment (but also see Wolpe, 1989), have included relaxation based techniques as control conditions in order to assess the additional beneficial effects of behavioral or cognitive treatment modalities. Other researchers (Borkovec & Costello, 1993; Ost, 1987) have employed relaxation protocols as treatments in their own right.

We will focus mainly on panic disorder, agoraphobia, and generalized anxiety disorder. Before reviewing work in these areas, however, the issue of whether relaxation training leads to any additional beneficial effects on fear reduction in simple phobias when compared to exposure alone needs to be addressed. McGlynn, Moore, Rose, and Lazarte (1995), in a study of clinically anxious snake-phobic students, reported that group abbreviated PMR training, in association with *in vivo* exposure, led to less behavioral avoidance, reduced autonomic activity, and lower levels of subjective distress compared to exposure alone. It would appear, therefore, that Marks had prematurely dismissed the potency of relaxation techniques in fear reduction.

The relationship between relaxation and exposure has been a focus of outcome research in both agoraphobia and panic disorder. Michelson, Mavissakalian, and Marchione (1988) compared paradoxical intention, therapist-assisted exposure, and relaxation on a range of outcome measures. Overall, the three treatments were equally efficacious and demonstrated significant improvements post-treatment and at a three-month follow-up. It should be noted that all groups underwent a general induction program that stressed the importance of self-directed exposure. In a later analysis, Michelson et al. (1990) examined differences in the three treatment modalities on psychophysiological processes and outcomes. Relaxation produced greater reductions in physiological arousal than did graded exposure, whereas paradoxical intention had no effect. However, despite earlier research indicating that patterns of synchrony–desynchrony might predict differential outcomes for these treatments (Turpin, 1990), no reliable relationships were obtained.

In a review of the treatment of panic disorder, Craske (1991) reports the superiority of a cognitive exposure group to relaxation alone on decreasing panic-attack frequency. However, relaxation was more effective at reducing general somatic symptoms and daily anxiety ratings during the course of therapy. Unfortunately, at 6- and 24-month follow-up, the relaxation group showed deterioration, while the exposure and combined exposure and relaxation groups demonstrated maintenance of therapeutic gains. Moreover, the relaxation alone group experienced higher attrition rates from therapy. In contrast, more positive results have been obtained by Ost and colleagues (Ost & Westling, 1995; Ost, Westling, & Hellstrom, 1993) using applied relaxation training (Ost, 1987). The first of these studies suggested that relaxation, exposure, and cognitive therapy were equally efficacious in the treatment of agoraphobia, if used in combination with self-exposure instructions. The more recent study attempted to replicate Clark et al.'s (1994) findings that cognitive-behavior therapy was superior to applied relaxation. Instead, Ost and Westling (1995) again reported generally equivalent outcomes for the two therapies. However, in agreement with the cognitive model of panic proposed by Clark (1986), the present study demonstrated that measures of cognitive beliefs predicted therapy outcomes, and this was equally true for both treatments. We discuss this finding further in the final section of this chapter.

Given the relative success of cognitive-behavioral treatments for agoraphobia and panic, psychosocial interventions have also been advocated for generalized anxiety disorder. Barlow, Rapee, and Brown (1992) compared relaxation, cognitive therapy, and their combination to a waiting-list control group. All three treatments were superior to the control condition on measures of worry and anxiolytic medication usage, and these gains were maintained at two-year follow-up. However, no differences emerged between treatment groups and following treatment most patients were left with significant residual symptoms. Moreover, the dropout rate was high among the active treatment groups. Similar results were obtained by Borkovec and Costello (1993), and indicated that cognitive-behavioral therapy (CBT) and applied relaxation were superior to a nondirective therapy control group. Some between-treatment differences did, however, suggest themselves. Applied relaxation appeared to favor greater reductions in daily anxiety ratings and diary measures, whereas CBT seemed more effective for worry and depression. At a 12-month follow-up, CBT showed greater maintenance of therapeutic gain (58% vs. 38% high end-state functioning) than applied relaxation. Following a review of existing outcome studies for generalized anxiety disorder, Borkovec and Whisman (1996) come to similar conclusions, and recommend a combination package of CBT and relaxation training, targeting both somatic and cognitive features of anxiety.

Finally, some mention should be made of outcome studies that have used nonrelaxation-based arousal reduction methods. Rice, Blanchard, and Purcell (1993) compared different biofeedback treatments (EMG and alpha EEG) with two control treatment conditions (EEG and pseudomeditation), and a waiting-list group. All four treatment groups, including the control treatment conditions groups, showed some improvement compared to the waiting-list control group. However, small sample sizes and a restricted number of treatment sessions limit the conclusions that can be drawn from this study. The utility of "mindfulness meditation" used in conjunction with a stress-management program for patients diagnosed with a variety of anxiety disorders (panic, agoraphobia, generalized anxiety disorder, etc.) is reported by Kabat-Zinn et al. (1992). In discussing the success of their program, the authors reflect on the potential benefits of "mindfulness meditation," and draw attention to the ability of clients to experience their thoughts directly as "just thoughts" in a nonreactive way, which leads to a decatastrophizing of the situation. It may be that this is a similar process identified by Borkovec and Roemer (1994) as "letting go" within applied relaxation, or the "effortless relaxation" discussed by Eppley et al. (1989) in relation to transcendental meditation.

6.09.4.2 Therapeutic Mechanisms

We wish to conclude this chapter by addressing the question of whether different therapeutic pathways can be identified, albeit rather speculatively, that share some commonality both within different arousal reduction methods and across cognitive-behavioral approaches in general. Starting with Lehrer and Woolfolk's treatment specificity position, which was derived from Davidson and Schwartz's specific effects model, we can classify a range of arousal reduction methods according to their putative therapeutic effects. Hence, progressive relaxation and biofeedback are essentially considered as somatic or physiologically oriented techniques, whereas meditation and cognitive stress management approaches are regarded as cognitive techniques. The logic of this model, therefore, is to match the therapeutic method to the presenting problem. Hence, it is suggested that somatically based treatments might benefit problems characterized by excessive autonomic and muscular arousal. Implicit in this approach is a rather simplistic opponent process model of therapy, whereby presenting problems are ameliorated by the addition of an opposing therapeutic component. However, recent outcome studies appear not to support such a simple relationship.

If panic disorder is considered, the specific effects model would specify that relaxation ought to target more somatic change, whereas cognitive therapy should give rise to greater attitudinal shifts, etc. Although there has been some support for this suggestion (Craske, 1991), in as much as relaxation was reported to bring about greater reduction in daily symptomatic ratings whereas cognitive approaches brought about a greater decrease in overall panic frequency, the majority of outcome studies have yielded more equivocal results. For example, Ost and Westling have reported that both applied relaxation and cognitive therapy yield roughly equivalent positive outcomes for agoraphobia. However, the major predictor of overall therapeutic outcome across both treatments were measures of cognitive beliefs (Ost & Westling, 1995; Westling & Ost, 1995). This would suggest that a common pathway involving cognitive beliefs mediated therapeutic change for both these interventions, as predicted by Clark's (1986) cognitive model of panic.

The question arises, therefore, of how the specific effects model can accommodate findings such as the above. The answer is probably to be found in more recent models of therapeutic change, which involve concepts such as emotional processing (Borkovec, 1994; Foa & Kozak, 1986; Rachman, 1980) and give rise to more dynamic explanations of change that involve an interplay between a variety of more discrete psychological processes such as physiological arousal, preattentive biases, affective response, associative networks, imagery, cognitive avoidance, worry, and extinction. The exact nature of the interplay depends on the therapeutic technique considered, together with the nature of the clinical problem. Within this context, we would argue that arousal reduction techniques might yield more subtle therapeutic gains through a variety of possible pathways. To illustrate this, we provide here some speculative examples of how relaxation techniques might yield the suitable conditions that bring about enhanced emotional processing and therapeutic change.

Before we can discuss the link between arousal reduction and emotional processing, we need to outline what is meant by the latter. According to Foa and Kozak (1986), emotional processing occurs when maladaptive fear structures are accessed in memory repeatedly, and fully processed, resulting in affective and physiological responding. In addition, this processing results in changes to the structure of the associative network responsible for representing the meaning of the fear object. With repeated exposure, together with full processing, extinction of the fear cues and their associations is brought about. Factors that are said to influence this process are level of arousal, early detection of threat cues, cognitive engagement and avoidance, depth of affective processing and emotional responding, worry, and distraction, together with overarching changes in attitude associated with mastery, coping, safety, and other metacognitive structures.

We would argue, therefore, that in the case of emotional disorder, arousal reduction techniques yield a variety of therapeutic effects through their ability to enhance emotional processing. We further speculate that these techniques provide several quite discrete mechanisms through which such facilitation might be achieved. These influences of arousal reduction techniques on emotional processing and consequent therapeutic change are outlined in Table 1. First, we suggest that the consequences of gaining competence in any arousal reduction/relaxation induction technique can be considered with respect to three general areas of functioning. These are direct changes in physiological activity, changes in ongoing attention and other associative processes (e.g., access to associative networks), and longer term cognitive, attitudinal, and behavioral changes.

Clearly, many relaxation techniques are said to result in altered physiological functioning, such as greater cortical deactivation, increased parasympathetic activity, decreased sympathetic activity, and lowered muscle tension. These changes may well be intrinsically therapeutic, since they represent direct therapeutic targets in their own right (i.e., reduced muscle tension, lowered blood pressure, etc.) and may also be associated with longer term physiological benefits with respect to neuroendocrine and immune functioning. We would argue, moreover, that these changes in physiological arousal may also lead to therapeutic changes within a second area of functioning known as "emotional processing." Several authors (Borkovec, Lyonfields, Wiser, & Deihl, 1993; Foa & Kozak, 1986; Shapiro, 1995; Turpin, 1991) have suggested that the depth of processing might be enhanced by relaxation. An associated observation from Borkovec's research is the observation that generalized anxiety disorder and worry are associated with autonomic inflexibility, and that therapeutic improvement is associated with an increase in parasympathetic activity. It is too early, however, to speculate about the direction of this relationship. Finally, the association with decreased arousal and extinction of fear has been fundamental to many accounts of desensitization (Lader & Mathews, 1970) and is still relevant to more contemporary models of fear conditioning (Davey & Matchett, 1996) and other therapeutic procedures such as eye-movement desensitization and post-traumatic stress disorder (MacCulloch & Feldman, 1996; Shapiro, 1995).

Table 1 Targets for potential therapeutic change arising from the implementation of arousal reduction techniques.

Physiological

Alteration of autonomic and endocrine functioning:
Central deactivation
Increased parasympathetic activity
Decreased sympathetic activity
Reduced muscle tension
Altered breathing
Endocrine changes
Immune function changes

Emotional processing

Changes in fear structures and memory:
Preattentive biases and early cue-detection of threat
Associative networks consisting of stimulus and responses propositions Accessibility to network and imagery
Changes in associative strengths and meaning
Cognitive avoidance and worry

Cognitive change

Changes in sensation, attributions, and beliefs:
Altered subjective experience of tension and calmness
Redistribution of focused attention
Reattributions of anxiety and panic cues/situations
Reduction in worry and metacognitions
Enhanced mastery and coping
Commitment to approach and direct exposure of feared object/situation

Changes in physiological activity may also be represented indirectly as altered interoreceptive feedback within a third general area involving cognitive change. Since it has been argued (Clark, 1986) that nonspecific bodily sensations might provide a cue for catastrophic attributions within panic disorder, any modification of these sensations, either due to relaxation or even medication, might have beneficial effects. This approach has been specifically developed further by Borkovec and Roemer (1994), whereby applied relaxation is combined with early cue detection and self-control desensitization. It would be expected that decreases in subjective bodily sensations and tension would also be accompanied by increases in subjective calmness, etc. Finally, a word of caution is warranted, since it has also been argued that a potential therapeutic strategy is to train clients to disattend to interoreceptive sensations (Wells, 1990). Somatically based relaxation techniques might contradict such an approach, and this may be apposite when clients occasionally experience relaxation-induced panic.

The extent to which interoceptive feedback or any other anxiety-related cues, such as distressing imagery or worrisome thoughts, are detected and attended to might also be affected by arousal reduction techniques. In particular, techniques that focus on cognitive strategies as a means of controlling, for example, worry, troublesome imagery, and unpleasant thoughts, such as guided imagery, autogenics, meditation, and hypnotic relaxation procedures, might also have an important role in emotional processing. Although these techniques may not necessarily have a direct facilitative role, they may be expected to have therapeutic benefits by counteracting other maladaptive cognitive phenomena such as worry and disturbing imagery which, according to Borkovec (1994), inhibit emotional processing. Worry is said to lead to cognitive avoidance, suppression of affective responding to imagery, delayed habituation, and the preservation of intrusive thoughts and images. The degree to which various cognitively directed relaxation strategies can result in a client gaining control of these negative cognitive strategies requires further confirmation and research. Interestingly, as discussed in Section 6.09.4.1, there are several different observations that have independently stressed the importance of decontextualizing negative thoughts or images by such techniques as "letting go," "effortless relaxation," "just thoughts," or "mindfulness meditation." Moreover, the therapeutic rationale provided with various relaxation techniques, together with the nature of the therapeutic relationship and the experience of therapy, should contribute to positive attitudinal change in relation to self-coping and efficacy, re-attributions of anxiety and panic, and overall changes in life-style and outlook. Indeed, Smith (1988) has emphasized the importance generally of the cognitive components of relaxation training and cognitive restructuring.

6.09.5 CONCLUSION

In this chapter we have attempted to provide a theoretical context within which different arousal reduction techniques might be evaluated. We have briefly reviewed the practical applications of these techniques and attempted some discussion of their relative efficacy, together with a review of the relevant outcome data. From this review, we would suggest that relaxation techniques have been shown to be beneficial for a variety of physical and mental health problems, particularly in the short term and during the course of ongoing therapy. Although other techniques involving more cognitively oriented approaches have tended to eclipse relaxation-based therapies, we would argue that therapists continue to give these methods serious consideration, particularly when used in conjunction with other cognitive-behavioral methods. This recommendation is based on evidence from outcome studies that have demonstrated a degree of efficacy, even for relaxation applied alone, and also from consideration of potential factors that might, albeit rather speculatively, affect the depth and efficiency of emotional processing.

> The meeting of two personalities is like the contact of two chemical substances: if there is a reaction, both are transformed. (C.G. Jung, 1933)

6.10.1 INTRODUCTION

Few would argue that the therapeutic relationship between client and therapist is the cornerstone of any psychotherapeutic modality. Whether one practices classical psychoanalysis or radical behaviorism, the practice of psychotherapy involves a relationship, an interaction, and an emotional exchange between two or more individuals. Regardless of whether or not the goal is in sight or is directed behavioral change, one cannot ignore the essential ingredient of the bidirectional influence of one party to the other within the therapeutic collaboration. With each client, the therapist must start from the beginning and build a relationship from the ground up. While the process of relationship building can become well developed over years of clinical practice, the therapist learns that each and every client requires the same regime. That is, to identify the needs of the client, discern the pathways to best relate to the client, and then use those pathways to establish and maintain the therapeutic relationship.

The therapeutic relationship has been addressed in the professional literature in a number of different manners (Alexander & Luborsky, 1986; Horvath & Greenberg, 1986; Safran & Wallner, 1991; Suh, Strupp, & O'Malley, 1986; Sullivan, 1954; Wright & Davis, 1994).

The therapeutic relationship typically involves factors of confession, atonement and absolution, encouragement, positive and negative reinforcement, aversive procedures, behavioral modeling, promotion of values, and cheer leading (Frank, 1985). What makes the therapeutic relationship different from a long talk with a close friend can be summed up in Frank's definition of psychotherapy. He states:

> Psychotherapy is a planned, emotionally charged, confiding interaction between a trained, socially sanctioned healer and a sufferer. During this interaction the healer seeks to relieve the sufferer's distress and disability through symbolic communications, primarily words but also sometimes bodily activities. The healer may or may not involve the client's relatives and others in the healing rituals. Psychotherapy also often includes helping the client to accept and endure suffering as an inevitable aspect of life that can be used as an opportunity for personal growth. (Frank, 1985, p. 50)

The relationship is not the reason that therapy can have a helping effect for an individual, but rather the vehicle and context that makes the probability of relief more likely.

This chapter will address four issues of the therapeutic relationship. The first focus will be to define and compare the view of the therapeutic relationship from different theoretical perspectives, including the Psychodynamic, Existential, Humanistic, and Cognitive-behavioral domains. The second area of focus will be to relate some of the empirical data on the therapeutic relationship and highlight the correlation between relationship factors and therapeutic efficacy. The third focus will be to identify and describe issues and circumstances that negatively impact on the therapeutic relationship, broadly termed resistance. Finally, we will address abuses of the therapeutic relationship and the impact that these abuses have on the therapeutic process. A final summary will attempt to integrate the factors discussed as well as review some general guidelines for the therapeutic relationship and the American Psychological Association's code for ethical behavior.

Early psychoanalytic work identified three relational components of the therapy process that had to be addressed in the therapy. The meaning, value, and importance of these factors has been the subject of debate for more than 100 years. Nevertheless, we can use them as a broad framework upon which to stretch the fabric of our discussion of the relationship in psychotherapy. These issues were termed transference, countertransference, and resistance. Broadly, they capsule the client's expectations, beliefs, reactions, and responses to the therapist and to the therapeutic environment (transference), the therapist's reactions and responses to the client's transference or, alternatively, the therapist's reaction to the client generally (countertransference), and the client's difficulty in therapy or avoidance of issues and areas of concern (resistance). These factors may be overtly expressed or more covertly expressed either subtly or symbolically depending on the particular client and the situation.

6.10.2 THE EXISTENTIAL PERSPECTIVE

Within the context of Existential Therapy the therapeutic relationship is one characterized by mutual respect, individual uniqueness, authenticity, and pursuit of meaning. According to Seguin (1965), 'It is through total acceptance, that the client comes to value his or her own uniqueness, becomes free to exert choice, to make commitments, and to find meaning in life." According to Bugental and Sterling (1995), it is necessary to develop what they term a 'meaningful realistic therapeutic contract." This suggests an agreement or arrangement (contract) between the parties and that the individuals involved both contribute and hope to gain from the arrangement. The therapeutic contract facilitates understanding between the client and therapist, rendering it meaningful and realistic. Bugental and Sterling (1995) further identify the existence of other therapeutic functions characterizing the therapeutic course. Besides developing a meaningful, realistic therapeutic contract, they propose the importance of 'Fostering the growth of a resilient alliance, working through the situational resistances, working through some of the character resistances, exploring client–therapist collusion (transference–countertransference issues), working with residual transferential elements and preparing for termination" (p. 240). The therapeutic contract is viewed as providing a foundation for therapy with the therapeutic alliance being conceptualized as a container that will hold the struggles, emotions, and relationships necessary to a major life undertaking. According to May and Yalom (1989), existentially oriented therapists strive toward honest, mutually open relationships with their clients. The therapist and client address one another equally, generally both on a first-name basis, with the therapist striving toward demystification of the therapy process, answering questions fully and openly, as opposed to remaining impassive in an effort to evoke transferential distortions.

The canon of humanistic existentialism is that the human element must be the focus of the therapeutic endeavor. No theory of the person, of therapy, or of pathogenesis can take precedence over the personhood and human elements. Further, those subscribing to a "scientific materialistic modality" as thinking about client's productions in atomistic terms such as units of energy, drives, impulses, needs, instincts, stimulus response links, or in transformation-of-energy terms lose the essence of the human element. For example, Ofman (1985) suggests that proponents of psychoanalysis will be guided by theory rather than by an attention to the person. He explains that the client should be seen in that (theoretical) light; taught that way of thinking (by the analyst); and the client's predictions will be traded in on the "quotidian" view because it is difficult for behavioral scientists to proceed otherwise. In Ofman's view, "Humanistic existentialism translated that position to dealings with clients, but not in counter transference terms. In such a translation there is not subject–object split, but there is a mutual process" (p. 12).

Within the context of the therapeutic contract/alliance, the existential therapeutic task is the fostering of explicit awareness. The goals are for the person to utter, clarify, and identify projects, and their personal myth; to assume ownership and responsibility for one's projects; to validate and embrace both the inevitable positive and negative aspects of relationships and of acts, so that the divided, unattended parts of the personality become integrated. The attainment of such goals leads to greater autonomy, responsibility, and an attendant equality in relationships. Progress toward these goals is sought by means of acceptance, affirmation, and authentic relating between therapist and client (Ofman, 1985). The authenticity can occur only when the therapist sees that the client has freely chosen to do and to be what they are, and to make choices for the best of all possible reasons, personal growth.

May (1969) states, "Intentionality presupposes an intimate relationship with the world that we would not be able to go on existing in except if we could block the world out at times. This should not be called simply by the condemnatory term 'resistance.' I do not doubt the reality of resistance, as Freud and other's elucidated it, but I am emphasizing here a broader, structural phenomenon. That is 'every intention is an attention, and attention is I-can,' as Merleau-Ponty puts it. We are, therefore, unable to give attention to something until we are able in some way to experience an 'I-can' with regard to it"(p. 36).

In essence, the Existential view places a major importance on the development of the relationship as central to the therapy. The relationship is famed in terms such as "real" or "authentic," with the realness of the therapist serving as both a model and guide for the client to emulate.

6.10.3 THE PSYCHOANALYTIC PERSPECTIVE

Munroe (1955) capsules Karen Horney's position by conveying that she believed that man was born a potentially harmonious organism, capable of expanding his own capacities normally, in happy relationships within his surroundings. Conflict, Horney believed, occurred only as a consequence of social mishandling which instituted exaggerated impulses and fears in contradictory directions. Normally, a child is confident of help from his parents, because he has experienced it regularly. The neurotic child believes he must fight for everything he wants in a hostile world, because he has experienced deprivation. Yet open aggression in a creature as helpless as the human infant brings swift and overwhelming counteraggression. Thus, aggression and the fear of being aggressive both develop to an exaggerated degree.

One important area addressed by Horney in the therapeutic relationship was her new perspective on the psychology of women. Tasman, Kay, and Lieberman (1997) identify very clearly that it was actually Horney who "argued that Freud's model of feminine development was phallocentric, a masculine fantasy that protected men from their unconscious fear of women. Horney's arguments have been of central importance in feminist critiques of Freud and ultimately in the reworking of views of feminine psychology within the mainstream of psychoanalysis" (p. 16).

Horney's therapeutic and theoretical approach was holistic and placed an emphasis upon the notion of self-realization as well as phenomenological and existential influences noted in her earlier works. Such a position is characterized by Horney (1945) in the following excerpt: "Freud's pessimism as regards neuroses and their treatment arose from the depths of his disbelief in human goodness and human growth. Man, he postulated, is doomed to suffer or to destroy. The instincts which drive him can only be controlled, or at best 'sublimated.' My own belief is that man has the capacity as well as the desire to develop his potentialities and become a decent human being, and that these deteriorate if his relationship to others and hence to himself is, and continues to be, disturbed. I believe that man can change and go on changing as long as he lives" (p. 72). Rejecting Freud's instinctual approach Horney stressed a stronger contextual stance as influential on the individual's development.

Tasman et al. (1997) make several cogent points that are important in understanding the therapeutic relationship:

(i) "Horney believed that humans were not the tragic figures that Freud depicted, driven by biological endowment to seek sexual and aggressive satisfaction and inevitably meeting conflict."

(ii) "Normal development was not inherently conflictual. The neurotic child sacrificed the pursuit of pleasure and the fulfillment of his or her unique potential which Horney termed the real self, to ensure safety in an environment that the child perceived as hostile and dangerous."

(iii) "Ultimately, neuroses was the result of the environment; the neurotic child responded to the parents' failure to love her or him as she or he was; and neurotic symptoms were importantly determined by cultural norms."

(iv) "Her emphasis on the current context of analysis has been absorbed into mainstream psychoanalysis; her concepts of the real self and human potential have contributed to the broader expanse of dynamic psychotherapies" (p. 96).

In the matter of issues directly involving the role of the analyst in the context of the therapeutic relationship, Horney (1939) writes: "When I feel uncertain about a suggestion made to the client I point out its tentative character. If then my suggestion is not to the point, the fact that the client feels that I too am searching for a solution may elicit his active collaboration in correcting or qualifying my suggestion." In effect, Horney takes the active position that the analyst should exercise a more deliberate influence not only on the direction of the client's associations but also on those psychic forces which cause the neuroses but also on those forces that may help him eventually overcome the neuroses. She further states that the work a client has to accomplish is most strenuous and most painful. It implies no less than relinquishing or greatly modifying all the strivings for safety and satisfaction which have hitherto prevailed. It implies relinquishing illusions about himself which in his eyes have made him significant. It also advocates placing his entire relations to others and to himself on a different basis. What drives the client to do this hard work? Clients come for analytical help because of different motivations and with different expectations. Most frequently they want to get rid of manifest neurotic disturbances. Sometimes they wish to be better able to cope with certain situations. Sometimes they feel arrested in their development and wish to overcome a dead point. Very rarely do they come with the outright hope for more happiness. The strength and constructive value of these motivations vary in each client, but all of them can be actively used in effecting a cure. Tasman et al. (1997) state, "The analyst should focus on the here and now, interpreting current wishes and defensive structures so the client's unconflicted potential could emerge" (p. 36).

Concerning Horney's views on the therapist's and client's direction in therapy, the following excerpt best illuminates Horney's position, "The aim of therapy is then not to help the client to gain mastery over his instincts but to lessen his anxiety to such an extent that he can dispense with his 'neurotic trends.' Beyond this aim there looms an entirely new therapeutic goal, which is to restore the individual to himself, to help him regain his spontaneity and find his center of gravity in himself" (Horney, 1939).

In an examination of issues of transference, Tasman et al. (1997) explain, "Although childhood influences shaped character, current defensive needs rather than infantile wishes were the chief determinants of current behavior and of the client's transference." Horney (1937) states, "In relationships in which one person becomes dependent on the other there is invariably a great deal of resentment. The dependent person resents being enslaved; he resents having to comply, but continues to do so out of fear of losing the other. When the fear is very great they may seek to protect themselves against this dependence by not attaching themselves to anyone. These processes are evident also in a client's attitude during analysis" (p. 24).

In a more traditional sense, "Resistance often uses the mechanism of transference as its weapon to interfere with the progress of analysis. In this, the client unconsciously strives to avoid the insight which the cure demands. The transfer of unconscious infantile wishes to the person of the doctor facilitates their admission into consciousness" (Eidelberg, 1968). According to Ferenczi and Rank (1925), the transference is an immediate goal of analysis; the replacement of the manifest neurosis by a transference neurosis. According to Horney (1937), "Transference (in the traditional sense) should refer to the sum total of all the client's irrational reactions toward the analyst, not only the emotional dependence. The problem here is not so much why this dependence takes place in analysis, because persons in need of such protection will cling to any physician, social worker, friend, member of the family, but why it is particularly strong and why it occurs with such frequency. The answer is comparatively simple: analyzing means, among other things, tackling defenses built up against anxiety, and thereby stirring up the anxiety lurking behind the protecting walls. It is this increase of anxiety that causes the client to cling to the analyst in one way or another." This view is emphasized in the following comment by Horney (1937). "Sexual desires concerning the analyst are usually interpreted as repetitions of a sexual fixation on the father or the mother, but often they are not genuine sexual wishes at all, but a reaching out for some reassuring contact to allay anxiety. The client, to be sure, often relates associations or dreams—expressing, for example, a wish to lie at the mother's breast, or to return to the womb—which suggest a father or mother transference. We must not forget, however, that such an apparent transference may be only the form in which a present wish for affection or shelter is expressed" (p. 48).

In a discussion of issues of transference infatuation, Horney (1937) points out that the analyst becomes cognizant of the impersonal character of the infatuation and attributes this indiscrimination to the client's tendency to repeat old patterns. The client feels relieved because he/she recognizes that there is something compulsory, something not genuine in his/her feelings of love. As a result, the actual infatuation diminishes, dependent on the analyst's strengths. The client's view may hold that his security and satisfaction may depend upon fastening himself to others or, more accurately, merging with them. Consequently, giving and hopefully obtaining affection is for him, a means of reassurance and thereby safety.

It would seem inconceivable that a therapy could begin or proceed without some level of anxiety being raised for the client. Anxiety may reflect the need to discuss personal issues and problems. It may also involve the need, expectation, or requirement that the client relate to the therapist. Whenever anxiety emerges, the client's need to hang on to the analyst intensifies. Therefore, whenever the client displays a more than usual attachment or transference reaction to the analyst, the analyst should connect and reflect the attachment back to the client as an indication of anxiety or insecurity.

The effect of this interpretation would be to open the gate toward a greater recognition on the client's part, and eventually to lead to an understanding of the underlying structure responsible for his/her anxiety reaction. As it is mainly the client's anxiety, according to the Horneyan view, which makes him dependent on the analyst, interpretations of this kind counteract from the beginning the danger of dependency.

On matters of resistance, Horney (1939) contends that when the client is analyzed, he/she will realize the futility of their efforts, though with some reluctance. He may politely and intellectually follow the analyst's suggestions that the irritations are only "bubbles" surfacing. But as soon as the analyst identifies one of the deeper disturbances, the client will react with a mixture of concealed irritation and diffuse anxiety, and soon will argue most cleverly that the analyst is wrong, that at least he is exaggerating his reaction. Resistance for Horney (1939) involves the energy with which an individual protects repressed feelings or thoughts against their integration into conscious awareness. This concept is based on our knowledge that the client has good reasons for not acknowledging certain drives and will seek to avoid them.

Regarding notions of countertransference and transference, Horney (1939) believes that when a therapist reacts with inner irritation to a client's tendency to defeat his/her efforts, he/she may be identifying the client with his/her own father, and thus repeating an infantile situation in which they felt defeated by the father. If, however, the therapist's emotional reactions are understood in the light of his/her own character structure as it is affected by the client's actual behavior, then it will be viewed as the therapist's need to cure every case. Failure to do so may be viewed as a personal humiliation.

In summary, Horney's view states that neuroses are ultimately the expression of disturbances in human relationships. The analytical relationship is a very unique form of human interaction. The therapy then becomes a microcosm of the client's relational life. Relationships and existing disturbances are bound to appear in the therapy as they appear elsewhere. The particular controlled and contained conditions under which an analysis is conducted render it possible to study these relationship disturbances more accurately than elsewhere. Finally, the relationship problems in the analysis can serve to convince the client of their existence and of the role they play in forming and maintaining the problems.

At the bottom is the question which is essential to the goals of therapy. Do we intend to put out a finished product with all problems solved for good and all? In fact, do we believe it to be desirable? Or do we think of life as a process of development which does not end and should not end until the very last day of existence?

The work of Harry Stack Sullivan is, by definition, based on the interaction between people. His work termed "Interpersonal Psychiatry" is representative of the Neo-Freudian factions of his time that espoused a collection of ideas that could be found operative within the context of the therapeutic relationship. Sullivan held the belief that human beings possess an actualizing tendency, that is to say, an innate predisposition for fulfillment of one's human potential. According to Mullahy (1970), Sullivan believed that there was a built-in tendency of the self to maintain its current organization and functional activity. Furthermore, by our very nature we would rather be healthy than to suffer from the pains of mental illness. Sullivan clearly recognized the importance of creativity, purposefulness, and in stressing a holistic approach in the treatment of his clients.

May and Yalom (1989) state that in the interpersonal model of personality an individual is not instinctually guided and preprogrammed, but is instead almost entirely shaped by his cultural and interpersonal environment. Hall and Lindzey (1970) regard personality as a hypothetical entity which is unable to be isolated from interpersonal situations and interpersonal behavior. It is all that can be observed as personality. In a sense, it is vacuous according to Sullivan to speak of the individual as the object of study because the individual does not and cannot exist apart from his relations with other people. Although Sullivan does not deny the importance of heredity and maturation in forming and shaping the organism, he contended that, that which is distinctly human is the product of social interactions.

Some believe that Sullivan's interpersonal psychiatry emphasized psychopathology as a personal method for coping with terrifying relationships. He believed that the therapist as a participant-observer offered a new mutative quality of relatedness to the therapeutic relationship (Greenberg & Cheselka, 1995). Sullivan believed in experience and cognitive processes as represented by three modalities: the prototaxic, parataxic, and syntaxic modes. According to Kaplan, Sadock, and Grebb (1994), the prototaxic mode is undifferentiated thought that is unable to separate the whole into the parts or to use symbols. This is something Kaplan, Sadock, and Grebb believe occurs normally in infancy and is also seen in schizophrenia.

Within the context of the therapeutic relationship we find that the process is a collaborative and active one. According to Kaplan et al. (1994), "The therapy process requires the active participation of the therapist, who is known as a 'participant-observer' " (p. 236). Modes of experience, particularly the parataxic, need to be clarified and new patterns of behavior need to be implemented. In his critical analysis of Sullivan's works, Mullahy (1970) states that the therapeutic relationship is a performance of two people, a transaction, in which the client's behavior and what he says and does are adjusted, in accordance with the best of his information and ability, to what he guesses or surmises about the therapist. In addition, the rationale of the interview is based on a progressively unfolding expert client (therapist–client) relationship for the purpose of discovering the client's characteristic patterns of living. The therapist seeks to discover those (frequently obscure) patterns of living of the client that he experiences as particularly troublesome as well as those he experiences as particularly valuable.

Within the scope of the therapeutic techniques, interrogation and interpretation warrant brief definition at this point. It was Sullivan's position to avoid direct interrogation. Sullivan viewed a direct question in a psychiatric interview as not likely to provoke the most informative answer. Rather, Sullivan would have the client test out hypotheses that would either support or disconfirm his/her existing thoughts on a subject which is more reflective of an indirect approach. Direct interrogative questioning was only to be used if there was a very justifiable reason and purpose. Mullahy (1970) writes, "The interrogation proceeds from a given point in a direction that is easy for a client to follow" (p. 16). Regarding the use of interpretations, they must be timely and accurate as well as and constructive. Further interpretation as a therapeutic strategy if used inappropriately might serve to fuel anxiety. According to Mullahy (1970), one must usually avoid questions and interpretations that arouse anxiety since, among other things, it provokes aspects that interfere with growth of the client's information and insight. Clearly if an untimely inappropriate interpretation is made and results in an unnecessary escalation of the client's anxiety, the therapeutic relationship could fall into serious jeopardy. Sullivan was aware that at times anxiety could serve a constructive function when it helped to mobilize a client. In general, however, he viewed it as a "formidable enemy" (Mullahy, 1970).

In reading Sullivan's works, one can see that his methodology represents an honest attempt at scientific inquiry. It is clear that his psychiatric interview is an attempt at the collection of relevant data. The results or accomplishments of the interview are to ensue partly from interpretation of clearly documented facts, from the building of inferential bridges that carry one from particular concrete instances to a generalized formulation, and partly from considering alternative hypotheses regarding situations in which the client has preferred misleading formulations. It was Sullivan's contentions that psychiatrists, particularly some psychoanalysts, were prone to interpretation of the material expressed by their clients and that the abundance of interpretations was greatly in excess of the need for them.

The therapist, within the context of the therapeutic relationship, seeks to facilitate identification and awareness of parataxic distortions and the development of insight into that process.

The notion of resistances were renamed "security operations" by Sullivan (1953). He felt that the discovery of a parataxic distortion brought about a sharp fall in one's level of security, causing one to become intensely anxious. This was viewed as injurious to the relationship, and ultimately to the therapy because, "the client's self-esteem, his interpersonal security, is often fragile or at least infirm, then, the disturbing consciousness of the 'mistake' tends to arouse essentially disintegrative, distance-producing security operations" (p. 34). The therapist must first be aware of the tendency for this to occur, be skilled in dealing with it, and to then intervene and counter the disintegrative operation.

For Sullivan, counter transference (in the classical Freudian sense) was the result of inadequate skill or some personal inadequacy (Mullahy, 1970). Sullivan did not believe a therapist should become seriously ego-involved with a client, and would, in fact, consider any personal involvement with his client therapeutically dangerous and part of what he termed "social hokum." For Sullivan, the key to the effectiveness of therapy was the interpersonal relationship. He saw the therapist as an expert in the problems that "ail" the client but did not recommend that the therapist become intimate with any of them.

Sullivan expanded upon and reformulated the notion of transference in terms of parataxic "me–you" patterns. He interpreted transference as a one-way process that showed the direct interaction of personalities. "By transference the client manifests interpersonal processes that open the gates of memory sealed by dissociations, reorients his experience, and facilitates the development of arrested or distorted systems of motives so that he moves forward toward the conditions of adult personality organization" (Sullivan, 1962, p. 87).

In the initial stages of the therapeutic relationship the therapist has the responsibility when the client presents a problem, especially in the early stages of therapy, to not arouse so much anxiety that the client feels threatened. This would occur before a client learned how to withstand a good deal of anxiety when experiencing any perceived attack on their self-esteem. In the initial stages of the therapeutic relationship, the therapist must ensure within the structure of the therapeutic situations that both the therapist and client can arrive at an agreement on the overall goal, end, or inclusive "purpose" of the therapy, so that there is collaboration.

Mullahy (1970) identifies that "Sullivan held that in the course of identifying all the more parataxically 'surviving,' unresolved situations of the client's past and their consequent dissolutions, there progressively occurs an expanding of the self to the extent that the client as known to himself is much of the same person as the client behaving with others. This was, for Sullivan, the therapeutic cure. Ideally, the client would achieve social cure (though not always the outcome) that might bring about a more abundant life in the community."

6.10.4 THE HUMANISTIC PERSPECTIVE

A discussion of the therapeutic relationship would not be complete without addressing Carl Rogers and his person-centered approach. Rogers was a major spokesman for the humanistic movement in psychology and led a personal life that reflected the ideas that he developed and used in his psychotherapeutic approach.

He displayed a questioning stance and a deep openness to change which spiraled person-centered therapy to a height of becoming a major force in psychology.

The goals of person-centered therapy differ from those of traditional approaches. The person-centered approach aims toward a greater degree of independence and integration of the individual in treatment. Its focus is on the person, not on the person's presenting problem. Rogers (1977) contends that his aim of therapy is not merely to solve problems, but to assist clients in their growth process so that they can better cope with problems they are currently facing as well as deal with future issues.

The specific role of the person-centered therapist is rooted in their ways of being and attitudes, not techniques designed to get the client to do something to change. Research on person-centered therapy indicates that the attitudes of therapists, rather than their knowledge, theories, or techniques, facilitate personality change in a client. Basically, the therapist uses himself/herself within the relationship as an instrument of change. Hence, encountering the client on a person-to-person level, their role as a therapist is actually to be "without a role." The main function then is to establish a therapeutic climate that helps the client grow in an individual way.

The therapist's role becomes essential in the person-centered modality in that it creates a helping relationship in which clients experience the necessary freedom to explore areas of their life that are now either denied awareness or distorted. A genuine aspect of the therapist's role involves the willingness to be real in the relationship wih a client instead of viewing him/her in a preconceived diagnostic fashion. In essence, the relationship then meets the client on a moment-to-moment experiential basis in an attempt to help them divulge their world. It is through the therapist's relationship of genuine caring, respect, acceptance, and understanding that they are able to help the client loosen their defense mechanisms and rigid perceptions in order to evolve into a level of personal functioning.

In his early work, Rogers (1961) wrote "If I can provide a certain type of relationship, the other person will discover within himself or herself the capacity to use that relationship for growth and change, and personal development will occur" (p. 33). It was Rogers' contention that the significant positive personality change of an individual occurs only as a result of the relationship between therapist and client.

The characteristics of the therapeutic relationship that are conducive to creating a suitable psychological climate involve creating an atmosphere in which the client will experience the necessity to initiate personalty change.

Rogers believed that the following six conditions were necessary and sufficient for personality changes to occur:

(i) Two persons are in psychological contact.

(ii) The first, whom we shall term the client, is experiencing incongruency.

(iii) The second person, whom we shall term the therapist, is congruent or integrated in the relationship

(iv) The therapist experiences unconditional positive regard or real caring and acceptance for the client.

(v) The therapist experiences an empathic understanding of the client's internal frame of reference and endeavors to communicate this experience to the client.

(vi) The communication to the client or the therapist's empathic understanding and unconditional positive regard is to a minimal degree achieved (Rogers, 1987, pp. 39–41).

Rogers hypothesized that no other conditions were necessary to facilitate change in the therapeutic relationship. He believed that if the aforementioned six conditions occurred over a given period of time, constructive personality change would occur.

In addition, three personal characteristics, or attitudes, of the therapist form the central part of the therapeutic relationship. These include congruence, or genuineness, unconditional positive regard and acceptance, and accurate empathic understanding.

One final important aspect of Rogers' work was that he believed that the therapist and the person of the therapist were the same individual. He believed that therapists should live their lives in accordance with theory which is used in the course of psychotherapy. Rogers believed this to be paramount in the therapeutic relationship.

6.10.5 THE BEHAVIORAL APPROACH

Clinical and research evidence suggests that a therapeutic relationship, even in the context of a behavioral orientation, can contribute significantly to the process of behavior change (Granvold & Wodarski, 1994). A good therapeutic relationship increases the chances that the client will be receptive to therapy. Not only is it important for the client to cooperate with the therapeutic procedures, but the client's positive expectations about the effectiveness of therapy may often contribute to successful outcomes as well. The behavior therapist is one who can conceptualize problems behaviorally and make use of the client/therapist relationship in facilitating change.

As opposed to some of the other modalities of treatment, behavioral practitioners do not assign an all important role to relationship variables. Instead, they typically contend that factors such as warmth, empathy, authenticity, permissiveness, and acceptance are considered necessary, however, not sufficient for behavioral change to occur (Bandura, 1977). It is not a matter of the importance of the relationship *per se*, but rather the role of the relationship as a foundation on which therapeutic strategies are built to help clients change in the direction that they desire. Lazarus (1989) maintains that unless clients respect their therapist it will be difficult to develop the trust necessary for them to engage in significant self-disclosure. At the same time therapists need an array of clinical skills and techniques to employ once an effective client/therapist relationship has been established. Since behavior therapy demands such a high level of skills and sensitivity as well as the ability to form a working relationship with clients, the therapeutic relationship is important. Behavior therapists tend to be more active and directive and can function as consultants in helping the client solve problems as opposed to allowing the relationship in and of itself to facilitate the change. Since behavior therapists use a coping model in initiating behavioral change in the clients natural environment, it is important that they be personally supportive to them. However, once again the actual process of change comes from the implementation of techniques as opposed to a byproduct of the actual relationship. At the very least, behavior tharapists view the relationship as being an important supportive aspect, yet not necessarily essential to change.

6.10.6 THE COGNITIVE-BEHAVIORAL PERSPECTIVE

Despite criticism by some in the field, cognitive-behavior therapy places an important emphasis on the therapeutic relationship as an integral part of the effectiveness in the treatment process. Constructs from cognitive-behavioral therapy can be used to understand variability in client behavior, and cognitive-behavioral formulations can be used to guide individuals in dealing with difficult problems in the therapeutic relationship. What is more, vicissitudes in the therapeutic relationship can provide individuals with an opportunity to work directly with clients' most significant maladaptive schemas which are an essential part of the therapeutic relationship. Schemas are defined as cognitive structures that may be at the core of an individual's particular dysfunction. It is a maladaptive, cognitive–interpersonal cycle that clients' perceptions of the therapist's behavior provide a phenomonological link to the dysfunctional interpersonal schemas and associated patterns of behavior (Safran, 1990; Safran & Segal, 1990).

The notion of an individual's maladaptive beliefs or schema was first proported by Beck, Rush, Shaw, and Emery (1979). Schemas, which are cognitive distortions at the individual's deepest level, consist of concepts that the client habitually uses in viewing reality. These biases direct their focus in the retrieval of information. Typical negative schemas include rejection, abandonment, control, uniqueness, and unrelenting standards—prime aspects that are found in any therapeutic relationship.

Therefore, a client who may maintain a negative schema of rejection will tend to focus on any sign that he or she is being rejected by the therapist. The same goes for their concept of abandonment and consists of what may be defined by the specific bias of their content. These schemas are usually formed during early childhood and selectively focus on information processing.

In his cognitive model, Beck, Freeman and associates (1990) used personality as a combination of core beliefs and a characteristic set of basic strategies for interacting with others. Inter-related beliefs and action plans are organized within a generic knowledge structure referred to in the cognitive literature as schema. These schemas guide and actively participate in the processing of information and actions so that we see recurring patterns of thoughts, feelings, and behaviors.

When deeply held beliefs and well-ingrained behavioral patterns are repeated in the therapeutic relationship and interfere with the effective use of what cognitive therapists refer to as collaborative empiricism, this creates a threat in the therapeutic process. The clients' expectations and perceptions of the therapist are typically distorted to remain consistent with his/her underlying beliefs. Behavior also remains consistent with dysfunctional beliefs. Cognitive-behavior therapists state that "cognitive transference develops when the aforementioned patterns are repeated in the therapeutic process (Wright & Davis, 1994). Cognitive-behavior therapists typically use certain procedures to identify and modify maladaptive beliefs and dysfunctional behavior when cognitive transference occurs. When an individual has a serious personality disorder, this process may require longer-term therapy than is usually the case with a major depressive or anxiety disorder.

The examination of beliefs, related behavioral strategies, and patterns in the therapeutic relationship can help therapists recognize and manage each client's unique expectations within the therapeutic process. It is extremely important that this be done and addressed forthright since any schema level analysis that is ignored may contribute to the clients' resistance and noncompliance and thwart the progress in therapy. In addition, excessive dependency or stagnation in the treatment process may also occur.

It is therefore that cognitive-behavior therapists emphasize the intense supervision on relationship issues in training programs (Michenbaum & Turk, 1987). In fact, it has been suggested that this element of the therapeutic process should require as much attention as learning how to implement specific cognitive and behavioral techniques (Wright & Davis, 1994).

The degree of importance of the therapeutic relationship depends not only on the approach, but in accordance with the complexity or the problem itself. The more specific and simple the problem, the more the therapeutic relation shall be of less importance. Results from a series of investigations give evidence to the importance that the therapeutic relation has gained as an instrument of social change. Sloan (1975) found that consultants who solved their problems satisfactorily through behavioral therapy considered the relation with their therapist as the most important factor in their recovery. Alexander (1976) reports that the therapeutic relationship contributed significantly to the behavioral treatment of delinquents and their families. Mathews et al. (1976) found that a group of agoraphobics considered that the support, enthusiasm, and sympathy received from their therapist helped them to overcome their fears more than the actual practice of exposure exercises. Researchers Orlinsky and Howard carried out a revision in 1986 about research undertaken in order to study the predictive capacity for diverse factors in psychotherapy with regard to their efficiency. They were surprised by the great predictive capacity shown by patients' feelings about the empathy shown by the therapist. This prediction went far beyond what could be done based on the empathy displayed by the therapist. In general, these results suggest that the interpretation which the client has on the actions of the therapist during treatment is a significant factor in the effectiveness of the respective treatment. The therapeutic relationship may therefore be used as a process facilitator of social influence of different forms.

In summary, the therapeutic relationship is an essential, interactive component of the process of cognitive-behavior therapy. Cognitive-behavior therapists need to remain sensitive to both the general and idiosyncratic expectations of their clients, without compromising the necessary limits or boundaries of the relationship. It is attention to these principles that will aid in building productive therapeutic relationships.

6.10.7 IMPEDIMENTS TO THERAPY

It is tempting (and simplistic) to blame treatment difficulty or lack of progress in therapy on the client's noncompliance or "resistance." Therapists may assume that when progress lags it is because the client does not want to change or "get well," for either conscious or unconscious reasons. However, there are many different problems which can slow or block progress in therapy and few of them are due to the client's desire to retain his or her problems. To illustrate this point, one might consider a "self-help" or "self-improvement" task such as losing weight, exercising regularly, or completing unfinished paperwork which one has been slow to complete. Is the lack of follow-through due to a secret desire to remain overweight, out of shape, or behind in paperwork, and to what extent might it be due to a number of more mundane factors such as personal comfort, time limitations, and so on. Might it be viable to assume that sometimes it is a combination of the two?

6.10.7.1 Definitions of Resistance

Common themes of client resistance in therapy involves distrust of the therapist, personal shame, grievances against others, depreciation, or fear of rejection. Typically, resistance may be manifested directly (e.g., tardiness or missing of appointments) or more subtly through omissions in the material reported in the sessions. A number of publications have addressed this important issue (Ellis, 1985; Shelton & Levy, 1981; Stark, 1994; Wachtel, 1982). There are, however, many reasons for noncompliance other than the client not wanting to change or the lack of compliance indicating a pitched battle between intrapsychic structures.

Clinically, we can identify several reasons for noncompliance. They can appear in any combination or permutation, and the relative strength of any noncompliant action may change with the client's life circumstance, progress in therapy, relationship with the therapist, and so on. We can divide these impediments to therapy into four broad categories. The first are problems emanating from the client. The second category include those problems stemming directly from the therapist. The third category pertains to those attributes involving the type, severity, and nature of the client's problem(s) or diagnosis. The final factors are those related to the client's life situation, personal context, and significant others. For each problem discussed, we will describe therapeutic interventions for reducing or ameliorating these obstacles and impediments to therapeutic change.

Resistance or noncompliance may take many forms. Some would appear more directly negative, for example, verbal evasion, verbal or physical aggression, or threats against the therapist or agency. Other forms of resistance may be more subtle, for example, lateness for appointments, missing appointments, extended silence in sessions, forgetting homework, or failing to pay the therapist's bill. And yet, others may appear positive, but still have the effect of resistance, for example, trying to win the therapist over with praise, gifts, or devotion. Resistance may be conscious, for example, withholding information and details to appear healthier, smarter, and so on. On the other hand, the same material might not be reported because of "forgetting," a process that might be more unconscious.

A starting point for understanding resistance is to conceptualize it as a normal and adaptive response to any type of perceived threat. Whether the resistant behavior is viewed as an ego defense or as a response to unfamiliar demands, it is unreasonable to accept that an individual will move directly to change without some level of discomfort. In point of fact, an individual who moves too quickly to change may be seen as impulsive or labile. An extreme to this would be the client with a borderline personality disorder who moves quickly from overidealization to complete devaluation. Normally, there is initially some hesitation with this process. Such resistance needs to be identified and addressed directly within the therapy process. Resistance is a predictable and therefore expected and at times even welcome part of the therapy. It can become an arena for the practice of a range of therapeutic interventions and in some cases adds to the change process.

Many of our clients have been involved in therapy prior to submitting to their present course of treatment. If the previous therapeutic experience has not been successful, it might be essential for the therapist to first assess what occurred in the previous therapy in terms of the focus, direction, content, timing, cadence, and style of treatment. With this information in hand, the therapist can then work to alter any and all of the factors emblematic of the previous therapy so that the present therapy is experienced as different, and not more of the same old pattern. For example, if the previous therapy was unstructured, structure would offer a different therapeutic experience and possibly draw forth new or different material. If the content revolved around a particular issue shifting to a variant of that issue, or even a different issue may be in order. The use of different examples would be useful in this regard. The short-term treatment approach is often enough of a different focus to make the therapy a new experience and opportunity for change. If the previous therapy was unstructured, structure would be helpful. If the previous therapy was a short-term treatment approach, the therapist must be even more creative in finding new directions or foci.

Use of the broad umbrella term of resistance may do more to limit therapy than to encourage or support it. Several reasons for noncompliance with a given therapeutic regimen may be isolated. It would be impossible to totally isolate each one as a separate and completely distinct entity from all others. There will, of necessity, be similarity and overlap. To make it easier to identify and deal with each, we have divided them into three categories, client factors, therapist factors, and problem or pathology factors.

6.10.7.2 Client Factors

(i) Lack of client skill
(ii) Client cognitions regarding previous therapy failure
(iii) Client cognitions regarding consequences to others of change
(iv) Secondary gain
(v) Fear of changing
(vi) Lack of client motivation
(vii) Negative set
(viii) Limited or poor self-monitoring
(ix) Limited or poor monitoring of others
(x) Narcissistic style
(xi) Client frustrated with lack of therapy progress
(xii) Patent perception of lowered status in therapy.

6.10.7.3 Therapist Factors

(i) Lack of therapist skill
(ii) Client and therapist distortions are congruent
(iii) Poor socialization to the model
(iv) Lack of collaboration/alliance
(v) Lack of data
(vi) Therapeutic narcissism
(vii) Poor timing of interventions
(viii) Lack of experience
(ix) Therapy goals are unstated, unrealistic, or vague
(x) Lack of agreement with therapy goals.

6.10.7.4 Problem/Pathology Factors

(i) Client rigidity foils compliance
(ii) Medical/physiological problems
(iii) Difficulty in establishing trust
(iv) Autonomy press
(v) Impulsivity
(vi) Confusion
(vii) Limited cognitive ability
(viii) Symptom profusion
(ix) Dependence
(x) Self-devaluation
(xi) Limited energy
(xii) Dissociation.

6.10.7.5 Client Factors

6.10.7.5.1 Lack of client skill

Therapists cannot make the assumption that every client has developed the skills to effectively perform a particular behavior or sequence of behaviors. For many clients their difficulty in therapy will parallel their inability to cope with life stressors. Both may be based on inadequately developed skills. These skills may be broad, that is, social skills, or more discrete, that is, making eye contact while speaking to another person. For many individuals, their skills may be adequate for "getting by" in familiar and highly structured areas of life experience, when their skills are tested in novel situations they have far more difficulty and may withdraw, or fail. If however, they are overtly successful at coping, they experience such a high level of discomfort that they will avoid future encounters. Given that the client may never have developed skills, or not developed them to the level necessary for adequate functioning, the therapist may need to teach particular skills to help the client move along in therapy and thereby in life.

6.10.7.5.2 Client cognitions regarding previous therapy failure

When the client has cognitions of failing to be able to successfully make changes in thought or behavior, the therapist needs to help the client to carefully examine their cognitions. Examining the cognitions, the underlying assumptions/schema and learning to respond in an adaptive manner to these negative and self-deprecatory thoughts, is a major goal of the therapy work. One aspect of "failure" which inhibits many clients is their anticipation regarding the therapist's reaction if homework assignments are not done "right." If the client anticipates receiving harsh criticism, anger, expressions of disappointment, or other aversive responses from the therapist when the homework is discussed, this can easily result in his or her avoiding the homework and coming up with excuses for not having done it. Obviously, it is important for the therapist to respond to noncompliance without being punitive or authoritarian and instead to work with the client to understand what blocked compliance. However, it is also important for the therapist to be alert for negative anticipation based on the client's previous experience with parents and teachers and to address these explicitly if they impede therapy. In particular, perfectionistic clients often anticipate extreme reactions if the homework is not done perfectly, and it can be quite useful to address these anticipations early in therapy.

Usually it is possible to honestly present the client's task as a "no-lose" situation by pointing out to the client that incidents of noncompliance or unexpected results provide opportunities for making valuable discoveries. For example, the therapist might follow the first homework assignment with, "One of the nice things about this sort of approach is that whatever happens, we come out ahead. If you go ahead and do [the assignment] and it goes the way we expect, great! We're making progress towards your goals. If you unexpectedly cannot get yourself to do it or if it does not work out the way we expect, then we have an opportunity to look at what happened and at your thoughts and feelings to discover more about what blocks you from your goals. If it goes smoothly we're making progress and if it doesn't, we're making a discovery." For many clients this greatly reduces the fear of failure.

6.10.7.5.3 Client cognitions regarding consequences to others change

Another set of cognitions involves the client having catastrophic ideas relative to the result of their attempting to change on others. The client often catastrophizes the result or consequences of their changing and needs to not only decatastrophize the potential, but to examine whether there are still advantages to changing.

6.10.7.5.4 Secondary gain

There may be situations where the client may not change because of the gain that accrues from continuing their dysfunctional suicidal thinking and/or behavior. In the case of suicidal behavior or ideation, this may force family members to treat the client with "kid gloves," not put any pressure on the client, avoid confrontation, and generally allow the client to do whatever they wished, rather than increase the suicidal potential. This gain may be obtained from family, friends, employers, or other individuals with whom the client has interaction. This client needs to look at the "primary loss" that goes into achieving their secondary gain. The client needs to be helped to achieve their gain in other ways.

6.10.7.5.5 Fear of changing

For some clients, changing means relinquishing ideas, beliefs, or behaviors that they see as inimical to their survival. While this may appear paradoxical in that their thinking makes them suicidal, these clients fear change as an unknown. They often choose the familiarity of their pain to the uncertainty of a new mode of thinking or behaving.

6.10.7.5.6 Lack of client motivation

Clients may arrive for therapy under protest. Therapy may be mandated as part of a legal penalty, that is, "go to therapy or go to jail." For other clients, therapy is coerced by family members, that is, "If you don't get help, I'm leaving you." For child and adolescent clients, the referral will come from the school or parents, that is, "You are in trouble and must change what you are doing, now."

In these circumstances, clients come to therapy with the message that the therapist is an agent of the referring (or coercive) individual, whether that individual is parent, spouse, judge, probation officer, guidance counselor, or teacher. This may facilitate an adversarial situation prior to the first therapy session, setting the stage for possible failure.

6.10.7.5.7 Negative set

Often a client is seen to have a "bad attitude," or "a very negative view." What is labeled as negative or attitudinal is often an issue of negative set. The negative set might be manifested directly as "Yes-but" behavior quickly disqualifying whatever the therapist says, or as directly arguing with the therapist on issues both large and small.

6.10.7.5.8 Lack of limited motivation

The reason for referral, the reasons offered for the client to change, the client's comfort or limited discomfort with behaving and feeling the way that they do, the level of dysfunction, and the press of demands of significant others all may work to reduce motivation. Often, the client may see small parts of the problems, but perceives them as "part of them," or as too small to bother with in therapy. The demands of therapy, cost, time, money and effort all further contribute to the limiting of motivation.

6.10.7.5.9 Limited or poor self-monitoring

Individuals may see the flaws and foibles of others, but remain blind to their own. Difficulty or inability to self-monitor will often be a major stumbling block to therapy. Being either unaware or unable to self-monitor and to then self-evaluate will lead to depressive affect and behavior. The client will often not self-monitor but will self-devaluate by developing and maintaining negative ideas about themselves.

6.10.7.5.10 Limited or poor monitoring of others

For some clients, the monitoring of others is a problem. They tend to look at others, but see very little. Their response to others would more likely be based on the client's images and distortions of others rather than a databased assessment. They will often see others as brighter, more attractive, more skilled, and so on. They will view all other relationships as more rewarding than any they have or might have, and do not seem to open their eyes to collect the needed data regarding others.

6.10.7.5.11 Narcissistic style

A narcissistic style needs to be differentiated from a diagnosis of clinical narcissism. The narcissistic style causes the client to be so self-involved that any attempt to have them look at others or at themselves is met with resistance. The reaction is typically framed as, "It can't be me," or "Why would you (or anyone) expect so much from me."

6.10.7.5.12 Client frustrated with lack of therapy progress

Clients may have unrealistic expectations of therapy and possible therapy progress. When the expectations are not met, the client may blame self or therapist for the lack of therapy progress and withdraw or withhold from the therapeutic collaboration.

6.10.7.5.13 Client perception of lowered status in therapy

For some individuals, being a client is a mark of lowered status. For many, being in therapy is the mark of being "sick," "disturbed," "weird," or "crazy." Given that belief, it would follow that leaving or avoiding therapy makes one less of all of the above.

6.10.7.6 Therapist Factors

6.10.7.6.1 Lack of therapist skill

Just as clients come into therapy with a particular set of skills, so too do therapists. Because of limited experience with a particular client problem or population, the therapist may not be best equipped to work with a particular client. The therapist working within the context of an agency or hospital setting may be able to call in colleagues for consultation on the case or to seek supervision on the particular case/problem. It would be incumbent upon therapists to constantly develop, enhance, and upgrade their skills through additional training. Post-graduate courses, continuing education programs, seminars, workshops, or institutes would be part of the professional growth of the therapist, no matter what their training. If the therapist's skills are poorly developed to effectively cope with a problem, transfer to another therapist is the ethical requirement.

6.10.7.6.2 Client and therapist distortions are congruent

This therapist blind-spot may be very destructive to the therapeutic process in that it would generally incline the therapist to accept the client's dysfunctional beliefs. If client and therapist share a particular dysfunctional idea, for example, "everything is hopeless and cannot change," it will bode poorly for the therapy. This sharing of an idea or belief can result in the therapist "buying into" the client's hopeless ideas and beliefs, not testing these beliefs, or even encouraging them.

6.10.7.6.3 Poor socialization to the treatment model

The client who does not understand what is expected of them will have difficulty complying with the therapeutic regimen. It is essential that the therapist assess the level of understanding of the model throughout the therapy work, especially with the suicidal client. Often their ability to listen and understand may be impaired by their hopelessness. The therapist cannot assume that having read books about therapy guarantees adequate socialization to therapy. Further, there may be proactive interference because of previous therapy. Clients who have been in therapy have, ideally, been socialized to that previous therapy model. They will continue to use the same strategies and approach to therapy and to life in general unless and until they are taught differently.

6.10.7.6.4 Lack of collaboration/alliance

Collaboration is an essential ingredient for all psychotherapy. This is crucial in working with the suicidal client. If the client and therapist do not have a good working alliance, it would seem to follow that the client may be less motivated to work with the therapist, do homework, follow the therapist's direction, or generally work towards making changes. The lack of collaboration, if not based on socialization difficulty or the skill of the therapist, may be due to the client's cognitions relative to cooperation or collaboration. Certain clients may actively work to thwart the therapist. This type of passive–aggressive behavior may be motivated by any of a variety of client cognitions, that is, issues of control, fear, competition, or displaced anger may all serve to cause difficulty in the therapy.

This client may be directly challenging or more covertly avoidant as in the classic "yes, BUT" response.

For example, a therapist in training asked for advice in handling a client's noncompliance with behavioral experiments designed to reduce the client's perfectionism. The client's goals for therapy were to resolve some relatively minor marital problems, but the therapist saw the client's perfectionism and the stress and job dissatisfaction which resulted from it as more significant problems. Rather than discussing this issue with the client and reaching an agreement on the goals of therapy, the therapist had unilaterally begun working on perfectionism and this led to the noncompliance.

Collaboration involves both the therapist and the client and either of them can disrupt it. If the client feels that he or she has no voice in how therapy proceeds, either because this is indeed the case or because of his or her beliefs and expectations, this is likely to interfere with collaboration and produce problems with compliance. It is important for the therapist to actively solicit and value the client's input in setting agendas, determining the focus of therapy, and developing homework assignments, particularly with clients who tend to be unassertive. It is also important to be alert for any cognitions on the part of the client which could block collaboration.

6.10.7.6.5 Lack of data

The basis for treatment is the assessment and general collection of data. The therapeutic conceptualization and the resultant treatment plan is then databased. If the therapy is focused on theory without data, the therapy will suffer. The therapist may then make major conceptual leaps without a solid footing upon which to base the therapy.

6.10.7.6.6 Therapeutic narcissism

An issue that can be a major impediment to therapy is what we term "therapeutic narcissism." This results from the therapist being so taken with themselves that they are blinded by the need for greater humanity and empathy. The therapeutic narcissism may take the form of telling rather than asking the client how they feel. It may take the form of deciding what the client needs without consulting the client.

6.10.7.6.7 Poor timing of interventions

Interventions that are untimely can have the effect of the client not seeing the importance or relevance of the therapeutic work, and thereby appearing to be noncompliant. If the therapist, because of his or her anxiety, tries to push or rush the client, the result may be the loss of collaboration, the missing of sessions, a misunderstanding of the therapeutic issues, or a premature termination of therapy, a possibly fatal issue with a hopeless client.

The timing and pacing of interventions can be quite important. If the therapist tries to push or rush the client, the result may be the loss of collaboration, poor compliance, poor attendance, or premature termination of therapy.

6.10.7.6.8 Lack of experience

Inexperience is something that all therapists face at the advent of their careers. This impediment is unintentional and a standard part of the mental health training system. Frontline therapists working with the most disturbed and problematic clients may be therapists in practicum, internship, or residency settings.

6.10.7.6.9 Therapy goals are unstated, unrealistic, or vague

When the goals of therapy are unstated, unrealistic, or vague, the client may be in the position of unknowingly resisting the treatment. This issue also raises problems with informed consent. The client must be part of the treatment planning process and informed as to the goals, strategies, and interventions of the therapy so that they can best comply rather than being noncompliant out of ignorance.

6.10.7.6.10 Lack of agreement with therapy goals

Obviously, the client who does not understand and agree to what is expected of him or her will have difficulty complying with the therapeutic regimen. However, it is easy for therapists to overlook the possibility that their instructions and explanations may not be understood and accepted by the client. It is important for the therapist to repeatedly solicit feedback from the client and to encourage the client to raise any concerns and objections, so that therapist and client can develop a shared understanding of the client's problems which forms a basis for collaboration and so that it is clear that the client understands and accepts the homework assignments. Generally this proves to be sufficient, but when the client holds strong preconceptions about therapy, the therapist may need to compromise to some extent in order to facilitate collaboration.

6.10.7.7 Problem/Pathology Factors

6.10.7.7.1 Client rigidity foils compliance

With some clients, their personality rigidity foils their ability to actively comply with therapy. This is particularly true with clients who are obsessive-compulsive, paranoid, among others, in which their disorder may preclude their compliance. They may question the therapist's motives or goals. They may be unable to break out of the rigid position that they see themselves as having to maintain.

6.10.7.7.2 Medical/physiological problems

It is essential for every client coming for therapy to have a complete medical evaluation, with blood work as part of a comprehensive assessment and treatment plan. It is unethical and dangerous for the therapist to be treating what may appear to be psychological disorders but have a medical etiology, for example, a client with hypothyroidism may appear depressed because of the slowed action and thinking. Conversely, hyperthyroidism might be confused with anxiety disorders.

6.10.7.7.3 Difficulty in establishing trust and cooperation

Trust is a central issue in therapy. The trust must be bidirectional where the client trusts the therapist and the therapist can trust the client. For clients where problems of trust are a diagnostic part of the disorder will have problems in therapy.

6.10.7.7.4 Press of autonomy

The autonomous individual will be reluctant to come for therapy. Their view is that if they cannot help themselves, how can anyone else help them. The idea of coming to someone's office at a time set by someone else's schedule, to talk about themselves is, at best, uncomfortable. Their avoidance of therapy is seen as one way of maintaining their autonomy.

6.10.7.7.5 Impulsivity

Clients who are impulsive, and this includes most children and adolescents, see therapy as restrictive and limiting. At best it is out of line with how they generally respond, at worst the therapy is seen as an onerous and problematic requirement that they cannot meet. Their standard and accustomed manner of response is to act without thinking and self-monitoring rather than to self-monitor and to think about actions.

6.10.7.7.6 Confusion

Clients who are confused because of schizophrenia, bipolar illness, or neurological injury or deficit will have difficulty making use of therapy. They may have memory problems, difficulty in follow-through, difficulty with homework, and problems dealing with any abstractions.

6.10.7.7.7 Limited cognitive ability

Clients may have limited cognitive ability that is a result of limited intellectual ability or neurological deficit. Their processing will be limited by the lowered level of cognitive integration.

6.10.7.7.8 Symptom profusion

Anxious clients will often overwhelm the therapist with graphic, elaborate, and detailed descriptions of their symptoms. Their idea is that if anything is left out they run the risk that the omitted piece will be the essential piece that makes it impossible for them to be helped. If part of their symptom picture is gastrointestinal distress, they will regale the therapist with images of their distress. The therapist will quickly learn more about the clients gastrointestinal tract than is necessary. They will often avoid therapy by speaking quickly to get it all in.

6.10.7.7.9 Dependence

The client who is dependent will often work to insure that the therapist is totally and completely on their side. They may overwhelm the therapist with data, bring the therapist gifts, or praise the therapist for the wit, insight, sensitivity, and perspicacity. The goal is closeness. Without the closeness, they believe that they will be injured or even destroyed. They are often frightened by short term therapy in that it means that in a relatively short time they will be without their helper.

6.10.7.7.10 Self-devaluation

Often termed low self-esteem or poor self-image, this involves devaluing everything that one does, or the concomitant overvaluing of what everyone else does (and therefore by comparison devaluing self). This often leads to "yes-but" behavior and to devaluing both the therapy and the therapist. This devaluation can be summed up by paraphrasing Groucho Marx's comment, "I would never join any club that would have me as a member." The therapist and the therapy are, by extension of working with the client, tainted.

6.10.7.7.11 Limited energy

Depression is a major contributor to this impediment. Individuals who are depressed will often have vegetative signs that include lowered energy. It then becomes difficult to cooperate in therapy given that the major goal is to avoid any activity that requires action or energy. Levels of energy both within the session, for homework, or for interpersonal relationships is minimal.

6.10.7.7.12 Substance use

If substance abusing clients come to therapy drunk or stoned, they cannot make use of the therapy. What may occur is state-dependent learning whereby they can only act in certain ways when under the influence of the substance. Clients who are semiaware or semirelated to the therapist will make little use of the therapy. When sober they either will not remember what was said or done or will have distorted it due to the filter of the drugs.

6.10.8 ABUSES OF THE THERAPEUTIC RELATIONSHIP

Smith (1988) writes, "The practice of psychotherapy involves much more than the mere application of psychological theory and techniques" (p. 59). The therapist–client relationship is a unique establishment of a working partnership with respect, trust, and confidentiality as its fundamental principles. This interactional process is the mechanism by which the effects of treatment are created and realized (Smith, 1988). As with most interpersonal relationships, the psychotherapeutic process has a frame or structure that delineates and identifies the purpose and meaning of the relationship. This frame consists of socially dictated components which serve as guidelines to how the therapeutic process should occur (Epstein, 1994).

Trust is an element of psychotherapy which is of primary importance. Clients expect that within reason, their needs are the focal concern of the therapeutic relationship, and that the therapist's responses and interactions have the intention of promoting effective treatment gains (Galletly, 1993). The ethical dictum is that the therapist must act so as to avoid injury or harm to the client.

The client has been encouraged to suspend their usual defenses, reveal deeply personal thoughts and feelings, and ultimately become somewhat dependent upon the clinician. The client enters treatment with the expectation of being helped. In addition, the client experiences the development of intense feelings toward the therapist as a manifestation of the transference. In this way, the therapist is in the position of power. The client becomes dependent, and depending on the presenting problems, possibly needy. The client is vulnerable to abuse. This abuse may take many forms from the more subtle (i.e., the therapist starting therapy sessions later than scheduled) through more moderate abuse (canceling therapy sessions) to the severe abuse of physical or sexual aggression. Sexual contact between a client and therapist will invariably cause situations that manifest themselves as the client experiencing greater difficulties with trust, self-esteem, and problems expressing anger (Simon, 1989). The clients usually feel exploited, used, and confused (Blackshaw & Patterson, 1992). Despite the documented harmful effects of sexual involvement with clients, 7–12% of therapists admit to having had sexual contact with a client (Gartrell, Herman, Olarte, Feldstein, & Localio, 1986). The gender breakdown of the therapists was approximately 10% of male therapists and 2–3% of female therapists having engaged in sexual activity with a client. Pope, Sonne, and Holroyd (1993) report that although the sexual exploitation of a client is the most explicitly defined ethical principle, it continues to be a problem within the mental health discipline.

Other areas of potential problems occur in regard to fees and financial arrangements. The Ethics Code for Psychology states that the psychologist as early as possible define and make an agreement as to how the fee schedule is arranged. Fees are consistent with laws, and are not misrepresented. Psychologists are permitted to use collection agencies (Canter, Bennett, Jones, & Nagy, 1994).

With regard to therapy itself, psychologists are required to advise the client as early as possible the structure and outline of therapy, confidentiality and its limits, and the proposed treatment plan. The psychologist is to provide coverage in the event of their absence, and terminate the professional relationship in a collaborative stance when it becomes evident that the client no longer requires the service or is not benefiting from continued treatment (Canter et al., 1994).

In conclusion, therapists are bound by clinical, ethical, and legal standards to maintain the integrity of the psychotherapeutic process. Epstein (1994) writes, "Ideally, the therapist will be able to fine-tune the frame into an empathic dynamic structure that is sensitive to the client's changing needs" (p. 17). The therapist is required to be not only competent in their chosen profession, but respectful, conscious of, and adhere to ethical standards espoused by their colleagues, licensing boards, legal mandates, and society as a whole in order to protect those vulnerable to potential harm. Gorton and Samuel (1996) propose that comprehensive training and mandatory education on the topic of sexual and ethical issues be included as a national requirement for graduate program accreditation.

The therapeutic work must take place within a working partnership with respect, trust, and confidentiality as its fundamental principles. This interactional process is the mechanism by which the effects of treatment are created and realized (Smith, 1988). Like every interpersonal relationship, the psychotherapeutic process has a frame or structure that delineates and identifies the purpose and meaning of the relationship. This frame consists of socially dictated components which serve as guidelines to how the therapeutic process should occur (Epstein, 1994).

Trust is an element of psychotherapy which is of primary importance. Clients expect that within reason, their needs are the focal concern of the therapeutic relationship, and that the therapist's responses and interactions have the intention of promoting effective treatment gains (Galletly, 1993). The ethical dictum is that the therapist must act so as to avoid injury or harm to the client.

The client has been encouraged to suspend their usual defenses, reveal deeply personal thoughts and feelings, and ultimately become somewhat dependent upon the clinician. The client enters treatment with the expectation of being helped. In addition, the development of intense feelings toward the therapist as a manifestation of transference occurs. In this way, the therapist, doctor, or psychologist is in the position of power, while the client assumes a more vulnerable position (Blackshaw & Patterson, 1992).

In addition, legal duties mandated by courts and statutes have further defined the psychotherapy relationship and the relevant and appropriate boundaries between the therapist and client. In sum, therapists are therefore accountable to professional, ethical, and legal standards (Simon, 1992).

The process of transference provides an avenue for either beneficial treatment to become actualized or noxious to the client by the therapist exploiting the established trust. In addition, countertransference, or feelings toward a client a therapist may have also become a mode of either positive or negative influence to the therapeutic process (Smith, 1988). The therapeutic relationship is described as fiduciary in nature (Simon, 1992). A fiduciary relationship exists when the client's compliance requires trust and vulnerability while the therapist's position renders a clearly influential role upon the relationship. The client relies on the therapist to provide treatment resulting in an asymmetrical or fiduciary relationship (Epstein, 1994).

6.10.9 GENERAL GUIDELINES

Sigmund Freud provided specific guidelines defining the ideal psychotherapeutic structure. Cited in Epstein (1994), Freud stated that his guidelines were imperative for creating and maintaining trust between therapist and client, and provided self-protection for the therapist. Freud advised that the client should receive informed consent explaining the nature of treatment. The therapist should practice abstinence and the nonexploitation of a client which included not confusing transference for real or true feelings or expressions toward the therapist (Lakin, 1991). The therapist should maintain a neutral stance including not advocating any one position or stance over another. The therapist should avoid dual agency or becoming involved with a client already personally known to the therapist. The therapist should practice relative anonymity and keep personal disclosures to a minimum. Finally the therapist should collect coherent and rational fees at regular intervals (cited in Epstein, 1994). Recently, Simon (1992) conceptualized treatment boundaries or frames necessary to maintain the integrity of treatment. These guidelines and principles mirror the ethical standards espoused by the American Psychological Association (APA). The most recent published set of APA guidelines are the 1992 version (Canter et al., 1994). Simon advises that the therapist must follow the guidelines below in order to create an effective ethical treatment process (Simon, 1992).

(i) Maintain therapist neutrality

(ii) Encourage psychological separateness between client and therapist

(iii) Maintain confidentiality

(iv) Secure informed consent for treatment

(v) Encourage verbal interaction with client

(vi) Ensure that no current or future personal relationship occurs with the client

(vii) Minimize or avoid physical contact

(viii) Preserve anonymity of the therapist

(ix) Establish and maintain a consistent fee policy

(x) Provide a safe, consistent, and private treatment setting

(xi) Provide clear definition of time and length of treatment sessions.

6.10.10 APA CODE

The 1992 Ethics Code of the APA clearly identifies general principles and ethical standards for all areas of psychological treatment.

The creation of the first formal APA Ethics Code was the result of the increasing professional activity of psychologists, both industrial and in mental health settings. As activity increased, regulations and guidelines were needed to ensure the integrity of treatment and the protection of all clients. The first Code was formulated from a critical incident method in 1948 which involved psychologists describing what they felt was an ethical situation or dilemma. The Ethics Committee of the APA then created a draft and final version of guidelines and standards in response to the previously identified situations from the empirical data obtained from the critical incidents listed and defined by psychologists. The first version was published in 1953, with subsequent revisions in 1958, 1962, 1965, 1972, 1977, 1979, 1981, 1989, and 1992 (Canter et al., 1994).

Following the outline of General Standards espoused by the APA Ethics Code, psychologists are expected to provide services for which they are competent based on their education and training. Continued training and education is required for the psychologist to remain in touch with current and updated treatment methods and research outcomes. The psychologist should speak with the client in a language understood by the client to ensure that informed consent has occurred. In this way, the client is aware and cognizant of the proposed treatment plan, procedures, or research (Canter et al., 1994).

Psychologists need to be aware of how human differences such as age, gender, race, sexual orientation, and disabilities can affect their work and recognize when they may or may not be qualified to treat any one particular individual. If this occurs, the expectation exists that the therapist will provide an appropriate referral to a competent therapist with the relevant expertise. Psychologists should always respect the rights of others to hold values, beliefs, or opinions different from their own. Psychologists do not degrade those of differing religious values, cultural or ethnic backgrounds, or politics. In this way, they are nondiscriminative (Canter et al., 1994).

Psychologists are prohibited from engaging in any form of sexual harassment, defined by sexual solicitation, physical advances, or verbal or nonverbal conduct that is sexual in nature that occurs in the therapeutic encounter. If a client has complained of being sexually harassed, the psychologist does not make prejudicial decisions in response to the client being a complainant, for example, denying admission to a graduate program. Additionally, psychologists are prohibited from harassing or demeaning clients in any form (Canter et al., 1994).

Psychologists must take reasonable steps and precautions to avoid harming their clients, and to minimize harm when it is foreseeable and unavoidable. In this way, psychologists must be able to recognize when their own personal problems or conflicts may interfere with their effectiveness as a treating clinician. If a psychologist is aware that their personal problems may be interfering with treatment, they are obliged to seek assistance and determine if they need to suspend or terminate treatment. A psychologist must also not misuse their influence upon a client, especially as the relationship between the therapist and client is asymmetrical with the position of power lying with the therapist (Canter et al., 1994).

The 1992 Ethics Code specifically prohibits the psychologist and client engaging in any type of multiple relationship. A psychologist must refrain from beginning a personal, scientific, professional, financial, or other relationship with a client as it may involve future harm or exploitation of the client. The Code does, however, recognize that in some rural areas of the country, situations in which clinicians who know the client before treatment begins may not always be avoided due to lack of resources. Psychologists are also advised not to barter with a client which means refraining from accepting goods or services as a way of paying for psychological services. The psychologist may, however, participate in bartering providing it does not cause the client harm, and does not involve any exploitation of the client (Canter et al., 1994).

Exploitation of the client is strictly forbidden in the Ethics Code. This includes not engaging in any sexual or personal relationship with students, supervisees, and clients (Canter et al., 1994). Clear evidence exists that clients are harmed.

In conclusion, therapists are bound by clinical, ethical, and legal standards to maintain the integrity of the psychotherapeutic process. Epstein (1994) writes, “Ideally, the therapist will be able to fine-tune the frame into an empathic dynamic structure that is sensitive to the client’s changing needs” (p. 17). This is essential, particularly since the therapeutic relationship plays such an important part as an agent in the change process.

ACKNOWLEDGMENT

The authors wish to acknowledge Gina Fusco, a doctoral student in clinical psychology at the Philadelphia College of Osteopathic Medicine, for her assistance with this chapter.

6.11.1 OVERVIEW

In the psychotherapy literature the main source of attrition in psychotherapy has been seen as dropouts during the acute phase of therapy. Rather less attention has been given to the problem of relapse and recurrence following sucessful treatment. However, since the late 1970s there has been an upsurge of interest in the long-term effects of psychological treatments and how treatment effects can be maximized and maintained. As will be demonstrated in this chapter there is still a considerable relapse rate associated with all treatments of psychological disorders including psychotherapy and pharmacotherapy. Cognitive therapy (Beck, Rush, Shaw, & Emery, 1979), behavior therapy (Wolpe & Lazurus, 1966) and interpersonal psycotherapy (Klerman, Weissman, Rounsaville, & Chevron, 1984) have all demonstrated some degree of efficacy in the acute treatment phase and also seem to have some preliminary promise in reducing relapse in certain clinical populations. However, the task of further reducing the still high relapse rates found in several disorders such as depression (Belsher & Costello, 1988) and substance abuse (Hunt, Barnett, & Branch, 1971) needs to be given serious attention by clinicians and researchers. In this chapter the relapse rates and predictors of relapse in a number of disorders will be reviewed, and the implications of this research for clinical practice will be outlined. A number of models of relapse that can guide reseach and clinical practice will be described. Attention will be given to the assessment of relapse risk and to planning treatment in a manner designed to reduce the risk of relapse. Relapse prevention and maintenance facilitating strategies will be outlined. Some concluding comments on the present status of maintenance and relapse prevention therapy procedures will be offered and future directions for research and clinical practice in this area will be suggested.

6.11.2 DEFINITIONS OF RELAPSE AND RECURRENCE

It is important to clearly define the terms "relapse" and "recurrence" as these are often used interchangeably. In the field of depression, Klerman (1978) has suggested that clinicians and researchers adopt the convention that the term "relapse" be used to refer to a return of symptoms within six to nine months after the onset of the index episode and that the term "recurrence" be used to denote a return of symptoms after a period of six or twelve months of remaining symptom-free. Klerman suggests that relapse may refer to continuity or re-emergence of symptoms of the original episode, while recurrence would be considered a new episode. Despite these guidelines there is still considerable confusion regarding this distinction in the literature.

Distinguishing between a chronic continuity of symptoms or behavior and a relapse following recovery or remission has been problematic in this field and made it difficult to establish accurate figures on relapse and recurrence. Designating patients as relapsed presupposes that they have experienced a recovery or remission from the original index episode. Recovery can be defined in a number of different ways. In the field of depression, for example, recovery is said to occur when the number and severity of symptoms falls below the threshold used for defining onset for a specified period of time (Keller, Shapiro, Lavori, & Wolfe, 1982).

Defining relapse can also be problematic. Brownell, Marlatt, Lichenstein, and Wilson (1986) have noted two different dictionary definitions of the term "relapse." The first refers to an outcome and defines relapse as "the recurrence of symptoms of disease after a period of improvement," and the second refers to a process, namely, "the act of backsliding, worsening, or subsiding." The outcome definition, often associated with biological or medical models, has very different implications from the process definition, which suggests that relapse involves a number of stages and is not a single event (Marlatt & Gordon, 1985).

Studies on long-term outcome in treatment often do not clearly specify the criteria used to define relapse. Also, since different studies do not utilize standardized criteria for recovery, relapse, and recurrence, comparing studies is difficult. Wilson (1992a) points out that there are many problems inherent in attempting to draw conclusions about relapse in psychological disorders due to the difficulty in drawing distinctions between lapse, relapse, and recurrence and clarifying the usage and measurement of these concepts in different disorders. Other methodological problems with the studies conducted in this field include inadequate cell size, differential attrition, failure to include control or comparison groups, and insufficient duration of follow-up.

6.11.3 REVIEW OF RELAPSE RATES AND PREDICTORS OF RELAPSE

6.11.3.1 Depression

A great deal of research has been conducted into the long-term outcome of depressive disorders (see also Chapters 3 and 16, this volume). The NIMH consensus panel (NIMH, 1985) concluded that as many as 50% of patients with recurrent unipolar depressive disorder who recover from an episode of depression will have a recurrence within two years. Other reviewers in this field (Belsher & Costello, 1988; Lavori, Keller, & Klerman, 1984) confirm these findings and additionally report a 20% relapse rate within two months and a 40% rate within a year. Approximately 70% of unipolar depressed patients respond to antidepressant medication in the short term but there is a considerable relapse rate with short-term pharmacotherapy (Ludgate, 1991). There is now an emerging body of evidence demonstrating that the use of maintenance medication (antidepressants or lithium) reduces the probability of relapse. Prien and Kupfer (1986) concluded in a review of this field that the risk of relapse was approximately 20% in patients continuing to take lithium or antidepressant medication compared to 50% who were switched to a placebo. Thase (1990) suggests that maintenance pharmacotherapy reduces the risk of recurrence over a two to three year period from 80% to 50%.

Behavioral approaches have shown some promise in producing positive long-term outcome and reducing relapse in depressed patients (Gonzales, Lewinsohn, & Clarke, 1985; Thompson & Gallagher, 1984). Social skills training has been found to be superior to both psychotherapy and tricyclic maintenance medication at six month follow-up (Hersen, Bellack, Himmelhoch, & Thase, 1984). Behavioral therapy was found to have a better course than pharmacotherapy, relaxation therapy, and nondirective therapy in a two and a half year follow-up of depressed outpatients (McLean & Hakistian, 1990).

Encouraging results have also been found using interpersonal psychotherapy with depressed patients (Weissman, 1994). Weisman, Klerman, Pruscoff, Shalomskas, and Padian (1981) found no difference between interpersonal psychotherapy and antidepressant medication at one year follow-up. Frank et al. (1990) used continuation interpersonal psychotherapy (on a monthly basis for 20 weeks) and antidepressant medication as a continuation treatment for unipolar depressed patients initially successfully treated with either interpersonal psychotherapy or medication. They found that maintenance medication had significant prophylactic effects and interpersonal psychotherapy had modest effects in reducing relapse risk.

A number of reviews (Hollon, Shelton, & Loosen, 1991; Ludgate, 1995; Wilson, 1992) have concluded that cognitive behavioral therapy has a prophylactic effect in the treatment of depression. It appears that patients treated with short-term antidepressant medication have roughly twice the relapse risk compared to patients receiving cognitive behavioral therapy (22–38% vs. 65–78%). In the NIMH study (Shea et al., 1992), cognitive therapy, interpersonal psychotherapy, and short-term Imipramine were compared. Relapse rates at 18-month follow-up were: 36% for cognitive therapy, 33% for interpersonal psychotherapy, 50% for Imipramine, and 33% for placebo. Return to treatment was significantly lower in the cognitive therapy group than in the other groups. In the only studies that compared cognitive therapy to maintenance antidepressant medication (Blackburn, Eunson, & Bishop, 1986; Evans et al, 1992), cognitive therapy still fared better in terms of relapse rates although the use of maintenance medication also resulted in relatively low rates of relapse. Wilson (1992b) concludes that cognitive therapy is at least as effective as maintenance medication properly maintained for one year. In all of the studies carried out on the long-term outcome of cognitive therapy for depression, no explicit relapse prevention or maintenance procedures are described. The therapy administered follows that described by Beck et al. (1979) and focuses on providing cognitive and behavioral strategies that aim to alleviate depressive symptomatology with the addition in some studies of booster sessions and some additional therapy (Blackburn et al., 1986). Only one study (Berlin, 1985) used an explicit relapse prevention focus and attempted to determine its effects. Self-critical patients were randomly assigned to standard cognitive behavior therapy or to a specifically designed relapse prevention program. Both treatments were equivalent in their effects on maintenance of treatment effects (reduced depression and increased self-esteem) at six-month follow-up.

Despite lower relapse rates in depressed patients treated with maintenance pharmacotherapy, cognitive therapy and interpersonal psychotherapy compared to other treatment methods, relapse is still a significant problem in this area.

Wilson (1992b) suggests that the following variables appear to put depressed individuals at greatest risk for relapse: chronicity, number of previous episodes, being in an environment of high expressed emotion or where a high number of critical comments are made by a spouse (Hooley & Teasdale, 1989), adverse life events, residual depression after treatment, posttherapy dysfunctional cognitive style (including the presence of dysfunctional attitudes and a negative attributional style), low self-efficacy concerning control over negative thoughts, dissatisfaction with major life areas, and coexisting medical problems. Other predictors for which there is at least some empirical support include endogenous subtype, duration of index episode, the presence of an Axis II disorder, higher levels of hopelessness at discharge, absence of social support, and persistent neuroendocrine dysregulation after recover (Belsher & Costello, 1988; Lavori et al., 1984; Ludgate, 1994).

6.11.3.2 Anxiety Disorders

While there has been a good deal of research carried out on the short-term effects of a number of therapies for anxiety disorders (see Chapters 17–22, this volume), there are few studies that provide outcome data on patients with anxiety disorders followed up for any significant period of time. Rappee (1991), reviewing research on generalized anxiety disorders, concludes that the positive effects of psychological treatments tend to endure over 6–12 month follow-up periods. In a three-year follow-up of generalized anxiety disorder patients receiving short-term stress innoculation training (Meichenbaum, 1977), Holcomb (1986) found that these patients required fewer hospital readmissions compared to patients receiving pharmacological treatment.

In agoraphobia, Telch, Tearnan, and Taylor (1983) found relapse rates of 27–50% in patients treated with Imipramine alone. Zitrin, Klein, and Woerner (1980) found that active psychotherapy methods such as exposure, when used in conjunction with Imipramine in the treatment of agoraphobia, reduces the relapse rate to 19% vs. 31% with Impipramine alone over a two-year follow-up. Encouragingly, Emmelkamp and Kuipers (1979) found that 60–70% of agoraphobic patients who responded to cognitive behavior therapy maintained their improvement at four-year follow-up. In treating panic disorder, medications such as Alprozolam and Imipramine have been found to be very effective at eliminating panic attacks in the short term but relapse rates of 70–90% following discontinuation have been found with Alprozolam and 35–40% with Imipramine (Brown & Barlow, 1992). A series of studies on cognitive therapy with panic disorder patients (Beck, Sokol, Clark, Berchick, & Wright, 1992; Clark et al., 1994; Craske, Brown, & Barlow, 1991; Ost & Westling, 1995) show impressively low relapse rates ranging from 0 to 19% in patients treated with cognitive behavior therapy whose panic attacks resumed in the follow-up period. In a review of behavioral treatments of agoraphobia, simple phobia and obsessive compulsive disorder with a follow-up period of at least one year, Ost (1989) reports relapse rates of 24% for agoraphobia, 4% for simple phobia, and 15% for obsessive compulsive disorder. Ost concludes that: further improvement after treatment is moderate in agoraphobia and obsessive compulsive disorder and nonexistent in simple phobia, overall about one-fifth of these patients relapse, and a large proportion seek further treatment. Ost (1989) describes a cost-effective maintenance program for anxiety disorders following initial behavioral treatment which is introduced in the last session of treatment when a contract to implement maintenance activities is signed by the patient. Over a six-week period following termination, the patient and therapist have 1.5–2 hours of telephone contact. Maintenance activities include: reviewing changes achieved and skills acquired during therapy, continued practicing of skills, distinguishing a setback from a relapse, identifying high-risk situations for relapse, and coping with setbacks. Results from three studies where agoraphobic panic and simple phobia patients completing this maintenance program were evaluated at 6–15 months, follow-up showed that overall, only 7% of patients relapsed and 10% needed further treatment, which compares favorably with the means of previously reported studies where 14% relapsed and 25% needed further treatment.

A number of longer-term follow-up studies have been conducted in obsessive compulsive disorder treated with cognitive behavior therapy. Rates of relapse reported are consistently in the 20–25% range in follow-up periods ranging from seven months to three years (Foa et al., 1983). Similarly, relapse rates of 20–30% have been reported over follow-up periods of up to six years following treatment by exposure therapy with this population (Emmelkamp & Kuipers, 1979).

While follow-up studies examining relapse and maintenance of treatment effects in patients with anxiety disorders are somewhat limited, the literature suggests that patients treated with cognitive behavior therapy have a lower risk of relapse compared to other treatment methods. However, as in the case of depression, a significant proportion of patients do not maintain treatment gains and experience a recurrence. There are few well-controlled studies that investigate predictors of maintenance and relapse following treatment for anxiety disorders. However, certain clinical characteristics have been implicated in poorer longer-term outcome. These include a comorbid diagnosis of a personality disorder (Turner, 1987), concurrent depression (Brown & Barlow, 1992), negative life events (Munroe & Wade, 1988), and interpersonal stressors and health problems (Tearnan, Telch, & Keefe, 1984) Rappee (1991) has hypothesized that information processing deficits are implicated in the long-term maintenance of generalized anxiety disorder. In the case of panic disorder, a cognitive factor, that is, misinterpretation of body sensations, is hypothesized to be involved in the etiology and maintenance of panic attacks (Clark et al., 1988), and this hypothesis has been given support in two studies which showed that higher scores on the Body Sensations Interpretation Questionnaire (Clark et al. 1988), an instrument which measures the tendency to misattribute sensations, were predictive of relapse at 15-month follow-up in panic patients who were panic-free at termination (Clark et al., 1988; Westling & Ost, 1995). In the area of obsessive compulsive disorder, Emmelkamp and colleagues (Emmelkamp, Kloek, & Blaauw 1992) have empirically demonstrated that life events, inadequate coping style, and high expressed emotion environments are predictive of relapse. In conclusion, though little systematic research has been done in this area, the following factors appear to increase the risk of relapse in anxiety disorders: comorbid depression or personality disorder, adverse life events, dysfunctional cognitive style after treatment, deficient coping skills, and a high expressed emotion environment.

6.11.3.3 Substance Abuse

The treatment of substance abuse has become increasingly more research-driven in recent years (see Chapter 25, this volume). Stimulated by the seminal work of Marlatt and colleague (Marlatt & Gordon, 1985), a good deal of research on relapse in addictive behaviors has been carried out. In this field, rates of relapse are disturbingly high across the spectrum of addictive behaviors (Marlatt & Gordon, 1985). Additionally, the temporal course of the relapse process is remarkably consistent across the various disorders. In a comprehensive review of a large number of treatment studies that followed successfully treated addictive behavior patients over a 12-month follow-up, Hunt et al. (1971) plotted survival rates for a number of addictive disorders and concluded that: the vast majority (65–75%) of treatment successes relapse within 12 months, two out of three relapses occur within three months, relapse rates seem to stabilize and plateau over time (after six months), and relapse rates and time to relapse are simular for heroin, nicotine, and alcohol addictions. Marlatt and Gordon (1985) confirm the finding that approximately two-thirds of all relapses across addictive disorders occur within 90 days of initiation of a treatment program or attempts at cessation. The high rate of relapse in addictive disorders is exemplified by research on smoking where as many as 88% of treated patients will relapse over a two-year period with the majority of relapses occurring within seven months with some stabilization of rates after 15 months (Brandon, Tiffany, Obremski, & Baker, 1990).

Marlatt and his colleagues (Marlatt & Gordon, 1985) have carried out extensive research into the predictors of relapse in addictive disorders. Based on an analysis of 311 relapse episodes obtained from patients with problems in the areas of smoking, drinking, gambling, and overeating, it was found that the following three factors accounted for over 70% of relapses: negative emotional states (e.g. frustration, anger, anxiety, depression, and boredom): social pressure; and interpersonal conflict (Cummings, Gordon, & Marlatt, 1980). In reviewing this area, Marlatt and Gordon (1985) note that there has been condiderable consistency found in studies examining predictors of relapse across various addictive behaviors. They further state that these three factors (negative emotional states, social pressure, and interpersonal conflict) appear to be the most frequently found high-risk situations for relapse in addictive disorders with urges and temptations, negative physical states, testing personal control, and positive emotional states being implicated in a somewhat smaller number of relapse situations.

6.11.3.4 Eating Disorders

Psychological treatments for eating disorders have grown in range and sophistication in recent years (see Chapter 29, this volume). A good deal of attention is now being given to long-term outcome in eating disorders although, as Orimoto and Vitousek (1992) note, these studies often track the status of diagnosed individuals over various time periods following diverse and often poorly specified forms of treatment, which makes comparison of findings across studies difficult. A review of the literature on anorexia nervosa suggests that a good long-term outcome is attained by roughly 40%, with 11–33% in an intermediate category and 14–42% judged to be doing poorly (Orimoto & Vitousek, 1992). Relapse rates following treatment are hard to estimate since a great number of anorexic patients do not attain recovery or remission after treatment and cannot thus be candidates for relapse by definition. Orimoto and Vitousek conclude that only roughly 50% of anorexics will eventually attain normal weight and menstruation and a significant subgroup will experience a relapse in the future, with the exact percentage of actual relapses being hard to ascertain.

Bulimia nervosa is a relatively recent diagnosis and the long-term course of the disorder is still being investigated. However, some tentative conclusions can be drawn from the literature. Approximately 53% of patients improve over 12–15 months without formal therapy (Mitchell, Davis, & Goff, 1985). However, only one-third of a large sample of treated and untreated patients remained abstinent from bulimic behavior over a one-year period (Mitchell, Davis, Goff, & Pyle, 1986). In addition Mitchell et al. (1986) found that as many as one-third of relapses take place within one month of treatment. Keller, Herzog, Lavori, and Bradburn (1992) found that one-third of bulimics remained in the index episode three years later and there was a cumulative probability of relapse of 63% over a follow-up of 35–42 months. Orimoto and Vitousek (1992) summarize the cognitive behavior therapy outcome studies carried out in this area and show a median figure for abstinence from binging and from purging of 61% and 45.5%, respectively, at follow-ups of three months and longer. They also suggest, based on some preliminary findings, that interpersonal psychotherapy may show some promise in preventing relapse and maintaining treatment gains. Few studies using cognitive behavioral methods have used treatment formats that use explicit relapse prevention procedures, and this is an area for further investigation following the promise of initial studies in this area (Fairburn, Kirk, O'Connor, & Cooper, 1986; Wilson, Rossiter, Kleifield, & Lindholm, 1986).

In the field of eating disorder, there are few systematic studies of predictors of long-term outcome following treatment. Keller et al. (1992) found that maintenance of recovery in bulimia nervosa could be predicted by less disturbed eating behaviors, more positive self-body image at intake, and having good friends. Mitchell et al. (1985) found that the antecedent conditions for relapse included coping with stressful situations (80%), feeling anxious or nervous (23%), and feeling depressed (23%). Root (1990) showed that triggers to relapse in bulimic patients were found to include inability to cope with feelings, attitudes that give rise to negative affect, and stressful events. Freeman, Beach, Davis, and Solyom (1985) found that body image dissatisfaction at the end of therapy was found to be the most powerful predictor of subsequent relapse. Cognitive states such as guilt and the tendency to make internal, global, and uncontrollable causal attributions for an initial binging have been found to be predictors of subsequent binge behavior (Grillo & Shiffman, 1994).

6.11.3.5 Overall Review of the Extent of the Problem of Relapse

Relapse rates following treatment have been well-established for depression. The incidence of relapse in depression has been shown to be reduced by the use of maintenance medication and psychosocial treatments such as cognitive behavior therapy and interpersonal therapy. Nevertheless, relapse still remains a significant problem (up to 50% over two years) in depression. High rates of relapse (of the order of 60–80%) and a short survival time (the majority of relapses occurring within three months) are consistently found in addictive disorders. Rather less is known about long-term outcome in the fields of anxiety and eating disorders, and so no firm conclusions can be drawn. However, clinical experience would suggest that relapse and recurrence are significant problems in these disorders too. There is a considerable economic cost involved in the still high rate of recurrence in psychological disorders. The human cost is also very high in terms of distress and demoralization for the relapsing patients, their families, and for the clinicians who treat them.

6.11.3.6 Review of the Predictors of Relapse

The prediction of relapse has a number of important consequences. First, it assists in our understanding of the fundamental processes responsible for change during and after treatment and on the nature of relapse. At a more practical level this work can help to identify individuals likely to show a poorer long-term response to treatment. This can help in treatment planning. Insofar as the predictors established are potentially modifiable (e.g., personal variables, such as dysfunctional beliefs or a poor sense of self-efficacy), these can become the focus of therapy in an attempt to prevent relapse.

Across the disorders reviewed there appear to be some common factors that put individuals at risk for relapse. These include negative life events, inability to cope with stress or negative affect, persistence of certain cognitive patterns or dysfunctional beliefs, and a low sense of self-efficacy. It could be postulated that the above risk factors may also predispose patients to relapse in other psychological disorders that are beyond the scope of this review.

6.11.3.7 Treatment Implications that Follow from Research on Predictors of Relapse

Research and clinical experience on relapse and its prediction suggest a number of rules of clinical practice, which if observed may lower the risk of relapse in patients with psychological disorders (Ludgate, 1995). The following strategies may be expected to facilitate maintenance and prevent relapse:

(i) cognitive distortions, dysfunctional assumptions, and other personal variables that can create a vulnerability to relapse should be dealt with prior to termination of therapy;

(ii) residual symptoms of emotional disorder, even those at mild or subclinical levels, should be targeted therapeutically prior to discharge;

(iii) patients who evidence high symptom levels and a maladaptive cognitive style post-treatment should be kept in treatment longer and maintenance therapy provided;

(iv) comorbid Axis I or Axis II disorders should also be addressed in treatment;

(v) general problem-solving and self-management skills with wide application should be practiced regularly during therapy, and a sense of self-efficacy should be fostered;

(vi) future life stressors should be anticipated and planned for where possible;

(vii) significant others should be involved in treatment, and therapy should focus on lifestyle modification, both of which may help to reinforce changes made in treatment.

6.11.4 MODELS OF RELAPSE

The importance of deriving treatment and relapse prevention methods from a coherent model has been stressed in several reviews in this field (Ludgate, 1995, Teasdale, Segal & Williams, 1995; Wilson, 1992a). A conceptualization of relapse benefits not only theoretical and research developments in this field but, most importantly, can guide clinical practice and assist in the development of rationally derived relapse prevention procedures. Finally, a coherent explanation of relapse can assist relapsed patients in making sense of this often baffling and mysterious process and, as a result, help generate both hope and a sense of control.

6.11.4.1 The Medical Biological Model

Until recently the predominant model of relapse was the medical biological view which stressed physiological or biochemical events that led to a return of symptoms or behaviors characteristic of the syndrome. This is seen in the definition of relapse as "the recurrence of a disease after a period of improvement." In the extreme version of this model (the disease model), a relapse into addictive behavior or into depression is an event over which the individual has little control as it is assumed that it is precipitated by physiological or biochemical changes that lead invariably to symptom re-emergence or behavioral loss of control.

This model has been criticized on a number of grounds including the charge that it ignores known psychological factors in relapse and induces a sense of hopelessness and helplessness in relapsed patients, stemming from the belief that they have no control over the relapse process, which may result in a further downward spiral of negative cognition, helplessness, and symptom recurrence (Marlatt & Gordon, 1985; Wilson, 1992).

6.11.4.2 Cognitive Behavioral Models

6.11.4.2.1 Marlatt and Gordon's model

Marlatt and Gordon's (1985) model of the relapse process in addictive disorders has had a major impact in the field of relapse prevention since the late 1980s. Marlatt and Gordon postulate that newly abstinent patients experience a sense of perceived control up to the point at which they encounter a high-risk situation, which most commonly entails a negative emotional state, an interpersonal conflict, or an experience of social pressure. If individuals cope effectively in the high-risk situation, perceived control and self-efficacy increase, which in turn makes the probability of relapse decrease. Conversely, the hypothesized result of a failure to cope with a high-risk situation is a decrease in a sense of self-efficacy, which in turn increases the probability of relapse. Each experience of successful or unsuccessful coping with a high-risk situation builds up a greater or lesser sense of self-efficacy, which determines the future risk of relapse in similar circumstances. Marlatt and Gordon (1985) contend that individuals' reactions to the initial slip and their attributions regarding the cause of the slip are the determining factors in the escalation of a lapse or setback into a full-blown relapse. The transition from slip or lapse to relapse involves the "abstinence violation effect," which results from a state of cognitive dissonance regarding the nonabstinent behavior and the individual's image of being abstinent. This dissonance can be reduced by either changing the behavior or changing the image, and characteristically in this population is resolved by the latter. Internal and stable attributes for the slip also lead to further lapse behavior. This model has received a good deal of empirical support and has the merit of dismantling the process of relapse and exploring subjective and cognitive variables in a manner that has important treatment implications.

Marlatt and Gordon (1985) argue that relapse prevention and maintenance should focus on teaching individuals who are trying to change their behavior how to anticipate and cope with the problem of relapse. Relapse prevention therapy should include: identification and preparation for high-risk situations; coping with negative emotional states, interpersonal conflict, and social pressure; training in general coping or self-management skills; slip recovery and relapse-crisis debriefing; programmed relapse and relapse rehearsal; lifestyle interventions; and education about the disorder and relapse. The use of Marlatt and Gordon's model in disorders outside the area of addictions has been advocated. Wilson (1992b) examines the possible role of this model in efforts to deal with depressive relapse. In particular he stresses the need to enhance depressed patients' sense of self-efficacy, and suggests strategies to foster this. Emmelkamp et al. (1992) have adapted this model in arriving at a cognitive behavioral model of relapse in obsessive compulsive disorder. Ludgate (1994) describes how many of the strategies described by Marlatt and Gordon are also applicable at various stages in the therapy of emotionally distressed patients.

6.11.4.2.2 Shiffman's model

Shiffman (1989) argues that the risk of relapse is related to the operation of three mechanisms: enduring personal characteristics (e.g., coping style and individual vulnerability factors such as low self-esteem); background variables (e.g., life events, relationship issues, mood, motivation); and precipitants (e.g., thoughts, feelings, and events that can lead to a relapse). Background and precipitating factors can both be viewed as high-risk situations. Background factors serve to "set the stage" for relapse and may reach a threshold level where relapse becomes more likely. How individuals react to these high-risk situations will influence where their level of relapse proneness crosses the threshold for relapse. The individuals' reactions to these situations will be determined by their coping skills, their sense of self-efficacy, and their expectancies regarding outcome and the effect of using their problem-solving skills. This model is useful in introducing the valuable concept of relapse proneness and the notion of factors from different domains mutually interacting, with a threshold for relapse being established by background variables. The treatment implications of this model are: first, background factors need to be identified, monitored, and modified in order to keep relapse proneness below a threshold level; second, enduring personal characteristics need to be worked on to reduce vulnerability to relapse; and third, precipitants need to be anticipated and planned for where possible.

6.11.4.2.3 Teasdale et al.'s model

Teasdale and colleagues (1995) have proposed a model of depressive relapse which attempts to explain the process of relapse in depression and also the mechanisms by which cognitive therapy achieves its prophylactic effects in the treatment of depression. This model involves an information-processing analysis of depressive relapse. It hypothesizes that following recovery, mild states of depression can reactivate depressogenic cycles of cognitive processing similar to those found during a major depressive episode. Teasdale et al. suggest that preventive interventions such as cognitive therapy operate by changing the patterns of cognitive processing that become active in states of mild negative affect preceding a full relapse into major depression. They suggest that the redeployment of attention utilized in stress-reduction procedures based on the techniques of mindfulness meditation (Kabat-Zinn, 1990) can be integrated with cognitive therapy procedures into a system of attentional control training. This approach would be applicable to recovered depressed patients and would serve as a means of preventing relapse. Teasdale and colleagues provide a description of this training which teaches generic psychological, self-control skills and can be used on a continuing basis to maintain skills after initial training. While no data on the effectiveness of this approach in preventing relapse exist to date, this appears to be a useful and stimulating conceptualization of relapse and relapse prevention that deserves further attention.

6.11.5 CLINICAL STRATEGIES TO REDUCE RELAPSE RISK

6.11.5.1 General Overview of Relapse Prevention Strategies

Maintenance and relapse prevention depend on the nature and natural course of the specific disorder involved, and the specific procedures selected to target relapse prevention and maintenance in therapy also need to be linked to a detailed case conceptualization for each patient (Persons, 1989). However, there are a number of strategies which might be expected to facilitate maintenance and prevent relapse across the various psychological disorders (Greenwald, 1988; Krantz, Hill, Foster-Rawlings, & Zeeve 1984; Ludgate, 1995; Marlatt & Gordon 1985; Miller, 1984; Shiffman, 1989). These strategies include:

(i) increasing patient responsibility within sessions and ensuring more between-session activities as therapy proceeds;

(ii) promoting internal attributions of change;

(iii) getting the patient to practice beyond a criterion (overlearning);

(iv) working on a variety of targets and providing training in general problem-solving or self-management skills;

(v) developing a self-therapy program for use after formal therapy ends;

(vi) helping patients anticipate high-risk situations and develop an emergency plan to deal with setbacks;

(vii) education regarding relapse, developing realistic expectations, and working on cognitions regarding possible lapses or setbacks;

(viii) assisting patients in recognizing early warning signs of possible relapse and intervening quickly and appropriately when these occur;

(ix) fading the frequency of sessions later in therapy;

(x) using booster or refresher sessions after acute therapy ends;

(xi) modifying the patient's lifestyle or environment to ensure reinforcement of changes made;

(xii) involving significant others in treatment.

6.11.5.2 Application of Specific Relapse Prevention Procedures at Different Points in Therapy

6.11.5.2.1 Assessing the risk of relapse

During the assessment phase and in the early stages of therapy, data should be collected to allow a comprehensive individual conceptualization which guides treatment planning (Persons, 1989). As a part of an overall comprehensive case conceptualization, a risk analysis can be carried out for each patient. This will include: an analysis of enduring personal characteristics (e.g., coping style, dysfunctional beliefs); background variables (e.g., life events, stressors); and possible precipitants to relapse based on the patient's history (i.e., events, thoughts, and feelings that could lead to a recurrence). In addition, the patient's sense of self-efficacy and their perception of their resources or skills to deal with life problems can be assessed at different points in therapy as new information becomes available. In the case of depression, a risk-analysis might be based on the following factors: number of prior episodes, duration of episode, comorbidity (especially Axis II disorders), coexisting medical conditions, post-treatment symptom levels, vulnerability factors (poor self-esteem, dependency), dissatisfaction with life areas, post-treatment cognitive characteristics (dysfunctional attitudes, attributional style), sense of self-efficacy after treatment, social support, and life stressors. Individual patients can then be characterized as a result of this case analysis as high risk (if a significant number of these factors exist), moderate risk (where several of these factors are in evidence), or low risk (where none of these factors are in evidence). The focus of therapy and the choice of treatment strategies can then be devised in the light of the assessment of relapse risk. This risk analysis also allows the therapist to make decisions regarding aftercare. Patients at high risk can be offered continuation therapy and, if possible, engage in active therapy even after symptom remission to work on relapse prevention and maintenance. Patients at moderate risk may be offered booster sessions while patients at low risk may have their last several therapy sessions spaced out before discharge and be invited back for occasional refresher sessions (Ludgate, 1992).

6.11.5.2.2 Early therapy activities

In the early part of therapy the "mental set" necessary for eventual maintenance and relapse prevention activities can be facilitated by stressing that therapy will be time-limited and that the goal is to provide methods that patients can subsequently use to "become their own therapist." Eventual termination should be discussed and the therapist should emphasize the importance of the maintenance and underscore the notion that therapy involves learning self-control methods which patients can use on their own after therapy ends. The therapist should also stress the importance of patients being active in the therapy process, practicing new skills, and setting agendas. This will help facilitate the shift later in therapy to patients working on maintenance and relapse prevention on their own.

6.11.5.2.3 Throughout therapy strategies

As an attempt to maximize the gains made in therapy, it is recommended (Ludgate, 1995) that throughout therapy attention be paid to the following:

(i) reviews of skills at regular intervals;

(ii) self-monitoring of progress;

(iii) overpractice of skills (overlearning);

(iv) teaching skills with wide application;

(v) generalizing skills or tools;

(vi) working at the schema or belief level and dealing with Axis II issues and comorbid diagnoses, where necessary;

(vii) dealing with vulnerabilty issues;

(viii) ensuring that the patient become more and more active in therapy;

(ix) increasing the emphasis on between-session behavior;

(x) fostering internal attributions for change; and

(xi) working on reactions to setbacks.

6.11.5.2.4 Pretermination procedures

In the later stages of therapy it is often beneficial to gradually taper off or space therapy sessions. There are three important therapeutic tasks to be accomplished prior to termination which may help reduce the risk of relapse. These are: first, developing a self-therapy or maintenance plan; second, reviewing skills learned in therapy and rehearsing the application of these to future high-risk situations; and third, learning to identify early warning signals of lapses or slips and developing an "emergency plan" to cope with these setbacks. A good rationale for maintenance activities needs to be given and thoughts and feelings related to continued self-therapy should be identified and restructured if necessary at this time. A list of possible helpful maintenance activities can then be drawn up collaboratively with the patient. To introduce the procedure of self-monitoring of early warning signals of relapse, the patient first needs to be socialized to the concept of relapse or recurrence as a process, not an event, and hence to the importance of early detection and intervention in the sequence. Using the patient's past history and the pattern of events in the most recent episode, it may be possible to come up with some key prodromal symptoms or behaviors that signal the beginning of the relapse process. A regular monitoring system carried out by patients themselves or by the therapist can then be set up to determine the presence of any of these early warning signs. Finally, a specific "emergency plan" can be generated before therapy ends, which should contain steps that can be taken in the event of symptoms or maladaptive behaviors reaching certain levels. It is also helpful at this point to discuss the criteria that will be used in making a decision to return to therapy or seek hospitalization.

6.11.5.2.5 Follow-up and aftercare activities

There are a number of options for the therapist in terms of aftercare activities. These include formal maintenance or continuation therapy, booster sessions, and refresher sessions. These decisions should follow from an analysis of the potential for relapse in each particular case. Maintenance or continuation therapy (Thase, 1990) is clearly the most intensive in terms of therapist time and effort and would usually be reserved for patients who are symptomatically recovered but at high risk for relapse.

The essential difference between continuation therapy and booster sessions lies in the frequency and duration of sessions and also in the content of these sessions. Continuation therapy involves working actively on areas of vulnerability, anticipating high-risk situations, and continuing to practice and overlearn skills. Booster sessions are focused more on reviewing progress and dealing with any residual problems or current difficulties experienced by the patient. Although reviews of the effectiveness of booster sessions have shown that the addition of these follow-up sessions are only moderately successful in maintaining behavior change (Whisman, 1990), there are some obvious advantages clinically to using booster sessions after the initial treatment has ended. Booster sessions encourage patients to take more responsibility in solving problems or managing their dysfunctional behaviors or mood states with the therapist's role becoming more that of a consultant or adviser. They also allow continuing monitoring of symptoms and appropriate intervention if necessary. Patients are more likely to be accountable in terms of maintenance activities if they know they will be reporting back on their progress in booster sessions. Whisman (1990) recommends that the natural relapse rate for the problem being treated be first determined, and maintenance sessions be scheduled during this high-risk period rather than arbitrarily scheduled. He suggests that the effectiveness of booster sessions can be improved by including the following components: a review of skills covered in therapy and problem-solving difficulties encountered in their implementation; teaching new or familiar skills to deal with problems arising during the follow-up period; reinforcing the individual's accomplishments and positive achievements as well as anticipating and planning for future stressors; encouraging individuals to involve themselves in self-help or community social support systems; and promoting lifestyle changes that are incompatible with relapse. Group refresher sessions may be an alternative to individual booster therapy sessions for patients who are doing well and have a somewhat lower risk of relapse. As described by Ludgate (1992), this is a cost-effective way to promote maintenance in former patients who are invited to attend group refresher workshops that review general strategies for solving problems, managing moods and stress, and changing behaviors. The emphasis is on skills rather than specific patient issues and these workshops focus on education and skill consolidation rather than therapy *per se*. In addition to being cost-effective in terms of the therapist's time, these workshops allow monitoring of former patients' progress, which can facilitate decisionmaking regarding the need for further aftercare interventions.

6.11.5.3 Working with the Patient who has Relapsed

The tasks facing the therapist in this situation are: to conceptualize and help the patient understand the relapse process, to re-instill a sense of self-efficacy, and to collaborate with the patient in generating a plan to recover from the lapse or setback. The extent and duration of the recurrence should be carefully explored in order to help distinguish a lapse from a full relapse. The task of the therapist and patient is to interupt the relapse process. It is important to explore patients' expectations regarding recovery, relapse, and the course of their disorder. If these are unrealistic, the therapist may help patients to substitute more realistic expectations. The therapist should help the patient "make sense" of what happened in this relapse episode, which will help to demystify the recurrence, give a greater sense of control, and encourage hope that the situation can be improved. The therapist should help foster external, unstable, and specific attributions regarding the relapse. The therapist can review with the patient strategies used during this episode and what impact they had. By a process of guided discovery the patient can identify skills learned in therapy that could be applied to this situation. A list of options can be drawn up to deal with the setback. It is important that the patient be as active as possible in the task of generating the remedial plan as this offsets hopelessness and increases the sense of self-control. Finally, patients can be encouraged to consider what has been learned from this experience and what they would do differently if faced with a similar situation in the future.

6.11.6 CURRENT STATUS AND FUTURE DIRECTIONS FOR RELAPSE PREVENTION

Since the late 1980s considerable progress has been made in the area of predicting relapse and in relapse prevention. While there have been appreciable advances in producing models of relapse and therapeutic methods to prevent relapse in addictions (Gossup, 1989; Marlatt & Gordon, 1985; Shiffman, 1989) and sexual deviancy (Laws, 1989), there is a need for clinical guidelines for relapse prevention in other fields such as depression, anxiety, and eating disorders. Some practical suggestions have been offered in the literature (Greenwald, 1988; Ludgate, 1994; Miller, 1984), but there are few specific guidelines for working with individuals with these disorders to promote maintenance and reduce the risk of relapse.

Studies are needed across all areas of psychological disorders that will employ more standardized utilization of relapse prevention strategies during and after therapy.

The development of treatment protocols for the continuation phase of therapy for patients at high risk is also a priority in this field. Research into factors involved in the maintenance of treatment effects and in the prevention of relapse is an important goal for both researchers and clinicians. There are a number of research questions that need to be answered by well-controlled studies. Wilson (1992a) argues that studies with long-term follow-up periods (e.g., three years or more) are needed, as few currently exist and most studies are confined to periods of 12 months or less. Research is also needed into the mechanisms responsible for relapse, or conversely for maintenance of initial remission. Clear predictions about conditions for relapse arising out of well-formulated theoretical models need to be made and empirically tested. Increasing our ability to predict the occurrence of relapse in particular disorders can be considered a high-priority task as it has obvious clinical implications in terms of treatment planning for at-risk individuals. Research into the development of valid and reliable measures of relapse risk is also an important research and clinical task at this time. Long-term outcome needs to be investigated in well-controlled studies which include clearly defined relapse prevention strategies applied in either the acute phase of treatment or during a continuation or maintenance phase of therapy following initial recovery. More research into the efficacy of booster sessions is needed and, in particular, into the optimal timing of booster sessions after treatment. Knowledge of survival time for a particular disorder may help to identify particular points in time for certain disorders when relapse is most likely and when booster sessions could usefully be scheduled. Wilson (1992a) advocates that several different types of relapse prevention procedures such as maintenance strategies integrated into the initial treatment program, boosters sessions and post-therapy, and minimal-contact procedures (self-help groups, telephone contact, bibliotherapy) be compared in terms of efficacy. To date, the shotgun or "more is better" approach appears to be the norm and research is needed on the contribution made by the different components of relapse prevention programs (e.g., anticipation and planning for high-risk situations, early detection of warning signals of relapse, programmed relapse, relapse rehearsal, self-efficacy training, lifestyle modification, and interventions for vulnerability issues). Studies that investigate predictors of relapse and sustained improvement, particularly therapy and patient factors that are amenable to change, are needed to inform clinical practice.

Pursuing some of the suggestions outlined above would serve to further expand some of the recent exciting developments in this crucially important field of maintenance of treatment effects and prevention of relapse.

6.12.1 INTRODUCTION

Review articles and meta-analytic studies have suggested that the use of self-help books (SHBs) is an effective adjunctive treatment in the practice of clinical psychology (Gould & Clum, 1993; Marrs, 1995; Pantalon, Lubetkin, & Fishman, 1995; Pardeck, 1990; Scogin, Bynum, Stephens, & Calhoun, 1990; Starker, 1986; 1988; 1990). In this chapter, SHBs will be broadly defined as the use of bibliotherapy and other written, psychotherapeutic materials that are usually read independent of a health professional. It seems likely that this effectiveness is due to the great appeal and availability of SHBs to the general public, including those who read them as study participants—more than 2000 SHBs are published annually (American Psychological Association, 1989)—as well as the study of SHBs which are based on empirically supported psychological interventions (see Gould & Clum, 1993). Whether based on their great appeal, effectiveness, or other reasons, SHBs are widely prescribed by psychotherapists to their patients. One estimate of the number of therapists who have ever assigned a SHB to a client is 60% (Starker, 1988), and the number of therapists who prescribe SHBs on a regular basis ranges from 55% to 88% (Marx, Gyorky, Royalty, & Stern, 1991; Starker, 1986, respectively). In addition, favorable therapist and client ratings of the helpfulness of a variety of SHBs has been documented (Starker, 1986, 1988).

Though the popularity of SHBs may have given rise to the empirical evaluations of their effectiveness, relatively few studies have been published on the critical factors which bear on their selection and appropriate use. Because information on these factors is unavailable, it is unclear whether the general public or the relatively large number of therapists who are assigning SHBs to their clients are selecting the most appropriate and/or effective SHBs. Another question regarding SHBs is whether their use is closely monitored by the prescribing therapist or whether they are merely suggested to clients, and not integrated into the course of therapy. Despite these and other unanswered questions, this author believes that SHBs have the potential to provide effective treatments, as well as to increase client involvement in the process of therapy and perhaps, improve its outcomes. These ideas are timely given the continued popularity of SHBs and the increase in managed care which sometimes severely limits the availability of psychotherapy sessions to its consumers. This author believes research on SHBs could be undertaken in a more systematic manner if the various types of SHBs available to the public were better defined and categorized, and if the degree to which readers follow the recommendations given in SHBs is assessed. Such improvements would allow empirical investigations of each type of book separately and comparisons among different SHBs, as well as information regarding the best way to use SHBs. This chapter will address these and other issues regarding the use of SHBs in the practice of clinical psychology.

There has been a long-standing controversy surrounding the use of SHBs. Rosen (1987) stated that SHBs "commercialize" (p. 46) psychotherapy by making overgeneralized statements about psychological problems and their causes, and by promising unrealistic results. He conjectured that this commercialization is mainly due to the market pressures to sell such books. Rosen believes that an SHB simply cannot present psychotherapeutic techniques in an adequate manner, and therefore unlikely to be sufficiently effective. Further, because SHBs may not accurately diagnose and because readers usually do not adequately comply with the recommendations therein, Rosen states that SHBs should not be used as a substitute for psychotherapy (Rosen, 1987). Although there have not been calls to have SHBs replace psychotherapy, this author agrees that the high degree of enthusiasm over some SHBs may have led to an overstatement of their effectiveness. Other authors disagree with Rosen's claims and suggest that an individual's ability to profit from a wide variety of SHBs is great (Mahoney, 1988; Starker, 1988). This author agrees with the statement that SHBs can be very helpful, but identifying the various conditions under which this can occur, and for whom, is crucial to advancing our knowledge in this area. This chapter will also attempt to address such issues.

In the following sections, this author will first categorize the various types of SHBs available today. Second, the available empirical studies on the effectiveness of SHBs, when used alone and with therapist contact, will be reviewed. Third, the great appeal of SHBs will be discussed along with the manner in which this appeal can be used to increase the understanding of and adherence to psychotherapeutic interventions, and can therefore enhance clinical results. Finally, this chapter will include a description of an approach for integrating SHBs into the course of psychotherapy, which could be applied to various forms of psychotherapy. Specific recommendations for selecting, assigning, and using SHBs in the context of a clinical practice will be offered, along with identifying both the client and therapist variables that appear to be crucial in the effective use of SHBs.

6.12.2 CATEGORIZATION OF SELF-HELP BOOKS

6.12.2.1 Standardized Therapy Manuals

Standard therapy manuals (STMs) describe a standardized treatment protocol to be used in conjunction with psychotherapy. They are therapist-directed and usually in an outline format. Both therapist and client versions are usually available. In essence, they are used as therapy guides. They are more technical than easy-reading, which differs from what one might generally find in a local bookstore in the self-help section. Marsha Linehan's (1993) treatment manual for borderline personality disorder is an example of an STM. Each chapter of Linehan's manual for dialectical behavior therapy illustrates in great detail the goals, methods, and objectives which will be used in treatment, similarly to what one would find in therapy sessions. It is considered a type of SHB because the client manual specifies tasks that clients can do on their own (e.g., homework). Other examples of STMs are *Mastery of your anxiety and panic* (Barlow & Craske, 1989) and *Problem drinkers: Guided self-change treatment* (Sobell & Sobell, 1993).

6.12.2.2 General Self-help Books

These do not address specific disorders, but rather general emotional, relationship, or life development issues without delineating specific techniques and homework exercises within a structured protocol. They are usually self-administered, but can also be therapist-assisted. Examples of such SHBs are *The road less traveled* (Peck, 1978) and *Notes to myself* (Prather, 1970). General SHBs can be used by therapists from a wide variety of orientations because they do not espouse any particular brand of therapy over another. Instead, they can be used to motivate clients to address problems which they may have avoided for some time or they can help clarify the goals and objectives of psychotherapy.

6.12.2.3 Problem-focused Self-help Books

These address a particular disorder (some actually assist the reader in diagnosing him- or herself) and delineate specific techniques and homework exercises within a structured protocol. They are usually self-administered, but can also be therapist-assisted. Examples of this type of SHB are *Stop obsessing* (Foa & Wilson, 1991), *Control your depression* (Lewinsohn, Munoz, Youngren, & Zeiss, 1992), *Coping with depression* (Blackburn, 1987), and *The feeling good handbook* (Burns, 1989). Although these are all examples of cognitive-behavior therapy (CBT) books, problem-focused SHBs are also written from a psychodynamic perspective (Bass & Davis, 1997). Problem-focused SHBs can be used by therapists with a wide variety of therapeutic orientations (e.g., behavioral, psychodynamic, interpersonal) for a wide variety of problems. However, it is advisable that they be used by therapists and clients who are prepared to systematically apply problem-solving and other techniques to a specific problem or symptom.

6.12.2.4 Technique-focused Self-help Books

These are similar to problem-focused SHBs, but instead focus on a specific technique, rather than a disorder, that could be used for several or many problems. Unlike the previous SHBs, these are usually therapist-assisted, because therapists are usually the ones to recommend these books to their clients. However, they can also be self-administered. Examples of SHBs are *The anxiety and phobia workbook* (Bourne, 1990) and *The relaxation response* (Benson, 1975). As above, these books can be used by therapists from a wide variety of orientations.

6.12.2.5 Internet Self-help Books

These are defined as any of the preceding SHBs that are found on the Internet. This category challenges the traditional notion of the genre that self-help is an individual helping him- or herself with the use of materials written by another or several individuals. Once this material is formatted for the Internet, however, the opinions, advice, and counsel of potentially thousands of other, mostly lay, but some professional, people can be accessed via chatrooms, message boards, and e-mail. The advice obtained from such sources can be quite personalized, because of the Internet user's ability to e-mail or post very specific questions about their condition and/or treatment. However, for the purposes of this chapter, it shall be considered self-help as long as individuals are not seeking direct consultation with a psychotherapist. Some of the examples of SHBs listed above are actually on the Internet (albeit in severely condensed form), but many Internet SHBs are not in the form of a book *per se*, but are rather in the form of a homepage with a myriad of options for further information or directions to other resources depending upon a reader's specific interests. These "books" are usually self-administered or with the assistance of "online therapists." The reader is referred to Dow, Kearns, & Thornton (1996) for a list self-help sites.

6.12.2.6 Educational Self-help Books

These attempt to help the patient, spouse, family member, or significant other learn more about the problems the identified patient is experiencing, and their prevalence, treatment, and course, as well as ways in which to effectively cope with the patient. This type of book is often helpful because it can shorten the educational process, allow patients and their families to become collaborators rather than passive recipients of treatment, and enhance adherence to treatment recommendations (Mueser, 1994). A number of such books have been written for many of the psychotic, affective, and anxiety disorders, such as *Surviving mental illness: Stress, coping, and adaptation* (Hatfield & Lefley, 1993) which pertains largely to schizophrenia, *When once is not enough: Help for obsessive-compulsives* (Steketee & White, 1990), or *Panic disorder: The facts* (Rachman & de Silva, 1996). A lengthier list of other organizations, SHBs, and resources for educating both patients and their families about psychological disorders has been prepared by Mueser (1994).

6.12.2.7 Other Self-help Books

Finally, there are some SHBs which do not fall into one of the above categories. These are books that are not explicitly intended as self-help, but rather are books (e.g., novels, biographies) which, for example, chronicle a well-known individual's life or attempts to cope with a particular problem which is in some way instructive, such as *Darkness visible* by William Styron (1990), Pulitzer prize-winning fiction writer. Most of these SHBs are self-administered, but when they are used with the assistance of a therapist, it is usually within the framework of psychodynamic psychotherapy (Pardeck, 1991). However, their use in other types of psychotherapy, as with general SHBs, is not contraindicated, because they usually serve to motivate efforts to change and give clients a lexicon with which to better describe their complaints. Unfortunately, there are no controlled studies, known to this author, testing the efficacy of this type of SHB. In the next section, the effectiveness of SHBs in general is reviewed, followed by a summary of the research on each of the above SHB categories.

6.12.3 OVERALL EFFECTIVENESS OF SELF-HELP BOOKS

Although the treatments found in many SHBs are usually not empirically supported, there are some significant exceptions and the number is increasing (Blackburn, 1987; Burns, 1989; Clum, 1990; Ellis & Tafrate, 1997; Foa & Wilson, 1991; Lewinsohn et al., 1992). However, even though there are some books which are based on empirically validated treatments, many of the SHBs themselves are not evaluated directly, though once again there are notable exceptions (e.g., Burns, 1989; Clum, 1990; Lewinsohn et al., 1992). For example, Foa & Wilson's (1991) book is based on a good deal of methodologically sound research study demonstrating the effectiveness of the techniques therein (e.g., graduated exposure with response prevention). However, the book itself (i.e., how the treatment works when a client reads about it and decides on his or her own to what degree he or she adheres to the recommendations) has not been empirically tested in controlled trials. However, others have been empirically tested in this manner, such as Burns (1989). Because an SHB presents psychotherapeutic techniques in a unique manner, it can have a very different impact on a client as compared with the impact of seeing a therapist, even if the therapist and the author of the SHB are presenting the very same techniques. This is true, in part, because rationales for the use of therapeutic interventions may differ significantly from those presented in an SHB, and because different rationales can lead to very different perceptions about treatment and outcome (Newman, 1994). For some individuals, the therapist could be more motivating because he or she represents another human being expressing understanding of the client's problems, but for others an SHB could be more effective because it is less personally threatening.

Gould and Clum's (1993) meta-analysis of 40 self-help studies resulted in a measurable overall effect size for self-help interventions of 0.76 at post-treatment and 0.53 at follow-up, which is comparable to those reported for psychotherapy (Stiles, Shapiro, & Elliot, 1986). This effect was strongest when SHBs were compared to no treatment conditions (e.g., wait-list and delayed-treatment controls) and when behavioral observations were used as the dependent measure (e.g., behavioral avoidance test). The lowest effect sizes were found when SHBs were compared to placebos (e.g., attention control conditions) and when physiological instruments (e.g., heart rate) were used as the dependent measure. Another meta-analysis, conducted by Marrs (1995), found a positive, though somewhat smaller effect size for SHBs (0.57), but no significant differences between SHBs and therapist-assisted treatments. In both of these more recent meta-analyses, SHBs for assertion training, anxiety, and sexual dysfunction were more effective than those for weight loss, impulse control, and studying problems.

Additionally, Gould and Clum found that the mean effect size for pure self-help conditions (with no therapist contact at all) was greater than that of the minimal therapist contact conditions (where therapists periodically helped patients with the materials). However, the mean effect size for self-help conditions was less than that of the therapist-assisted conditions. The mean effect size for self-help conditions (SHB assigned with no therapist contact) was also less than that of the combination of self-help and therapy (assignment of an SHB plus periodic therapist supervision). An important difference is that SHB plus therapy was a more intensive integration of therapy and self-help regimens than the minimal contact conditions. Obviously there is a need for more research in this area so that a definitive statement about usefulness of SHBs and their combination with psychotherapy can be made. Interestingly, in the Marrs (1995) study, the amount of contact the therapist made with participants in SHB-only conditions was not significantly correlated with outcome. However, it appeared that participants whose primary goal was weight loss or anxiety reduction improved significantly more with increased therapist contact.

Thus, it appears that there are mixed results when comparing self-help vs. therapist-assisted conditions. One hypothesis, put forward by Gould and Clum (1993) is that the therapist-assisted conditions may not adequately resemble how a therapist would actually assist a client with an SHB in therapy and therefore may not have enhanced the SHBs effectiveness; it may have even diminished it to some degree. One factor that may have influenced these results is the fact that only 15 of the 40 studies analyzed by Gould and Clum utilized a clinical sample and it is unclear whether SHBs would be as effective with patients who consistently met specific diagnostic criteria.

Although Marrs (1995), based on a sample of nine studies, found that there was no significant difference between SHBs and therapist-directed treatments, a definitive statement about whether SHBs are more or less effective than therapy cannot be made because of the small number of studies that compare active treatment without an SHB to (i) self-help in general (only nine were included in Marrs' study), and (ii) pure self-help conditions (no therapist contact).

6.12.4 EFFECTIVENESS OF EACH TYPE OF SELF-HELP BOOK

6.12.4.1 General Self-help Books

Although general SHBs sometimes focus on a particular area of an individual's life, the exact nature of the problem is ill-defined (e.g., low self-esteem, failed relationship), and they do not assist a reader in ascertaining a proper diagnosis. Such books also do not offer specific techniques and homework exercises within a structured protocol. For these reasons, these books are simply more difficult to assess in terms of effectiveness. They are often based on the clinical intuition and nonempirically based theories of the author. Another reason why they are difficult to investigate in research is that the advice described within them often appears to be overgeneralized and superficial. Despite the above shortcomings of general SHBs, their popularity is staggering. However, this popularity has not prompted much empirical investigation, and thus, very little data are available regarding the impact of these books (Starker, 1990). Therefore, it would be difficult at this stage to even recommend how they could be integrated into the context of psychotherapy or for what problems. However, it appears that such books (e.g., Peck, 1978) could be effective in helping a patient clarify exactly what thoughts, feelings, and/or behaviors are most distressing. They could also assist the therapist and client in setting goals and objectives at the outset of therapy, especially if the client is unclear about how he or she hopes to benefit from the experience. Such books have been described as being helpful in treating physically and/or sexually abused or neglected children (Pardeck, 1991), though only one controlled trial has been conducted (Ogles, Lambert, & Craig, 1991), which demonstrated that a general SHB worked equally well as behaviorally and stage theory-based SHB for coping with divorce. General SHBs seem to be utilized mostly by therapists who are experientially, Gestalt, or psychodynamically oriented therapists (Pardeck, 1991). This may be because these SHBs focus on events (current and/or historical) which are thought to be the cause of the problem behaviors, rather than on specific procedures to ameliorate them.

6.12.4.2 Problem-focused Self-help Books

There are a number of other studies that demonstrate the effectiveness of problem-focused SHBs for particular disorders. Regarding depression, it appears that reading a cognitive or behavioral SHB is more effective than delayed-treatment groups (Scogin et al., 1990; Scogin, Jamison, & Gochneaur, 1989; Smith, Floyd, Scogin, & Jamison, 1997; Wollersheim & Wilson, 1991), equally effective as group CBT (Wollersheim & Wilson, 1991), and that cognitive and behavioral books were also equally effective (Scogin et al., 1989). Treatment gains have reported to be maintained or enhanced as long as three years beyond the end of self-help treatment (Smith et al., 1997). Additionally, Mahalik & Kivlighan (1988) reported that participants who are high on measures of independence, need for structure, internal locus of control, and self-efficacy, had responded better to a self-help approach to depression, than those who were low on these attributes.

Regarding panic disorder, Ghosh and Marks (1987) found that self-exposure instructions worked equally well to reduce anxiety when given by a psychiatrist, SHB (*Coping with panic* [Clum, 1990]), or computer program, and that each resulted in substantial improvement up to six-month follow-up. Gould, Clum, and Shapiro (1993) similarly found that the effectiveness of an SHB was not significantly different from that of individual guided imaginal coping. Both treatments were significantly more effective than a wait-list control group. In a follow-up to the above study, Gould and Clum (1995) concluded that the SHB *Coping with panic* (Clum, 1990) was significantly more effective than a wait-list control group at post-treatment and at two-month follow-up. Lidren et al. (1994) also report that *Coping with panic* is as effective as group therapy based on the same book, which was required reading, and more effective than a wait-list control.

Ogles et al. (1991) report findings from one of the few studies to compare problem-focused books based on different therapeutic orientations, namely behavior therapy and stage theory for the treatment of reactions to divorce. These books were also compared to a general SHB, which focused broadly on coping with life events (not only divorce). It was found that all three were effective in reducing a variety of symptoms associated with loss, but that they all worked equally well. In addition, those who reported high expectations of being helped fared better than those who did not, as evidenced by greater reductions in symptom scores, and attributed the change largely to their reading of the books.

Other behaviors, such as problematic drinking (Heather, Robertson, MacPherson, Allsop, & Fulton, 1987; Hester & Delaney, 1997; Miller & Taylor, 1980; Sobell & Sobell, 1993) and smoking cessation (Glasgow, Schafer, & O'Neill, 1981) have also been shown to be modifiable with the use of SHBs. Heather et al. (1987), in particular, demonstrated that a problem-focused book on controlled drinking was more effective than an educational book regarding alcohol problems. In addition, many of these studies report maintenance of gains at six months, and one, two, and three years. Hester and Delaney (1997) and Gould and Clum (1995) have also demonstrated that computerized SHBs are also effective.

In summary, the SHBs in this category which have some level of empirical support have been based predominantly on CBT. Thus, more research is required in other areas, as meta-analytic studies inform us that overall, most psychotherapies are equally effective (Stiles et al., 1986). SHBs, based on other models of psychotherapy, could thus prove as helpful as those above. However, the books that take up the most space in the self-improvement section of a local bookstore (e.g., SHBs on dieting, relationships, parenting, hypnosis), or have been found to sell the best (Starker, 1990) are not the ones that have been empirically validated directly, nor are they based on treatments shown to be effective in research studies (Marrs, 1995). Conversely, some SHBs that are based on empirical data do not sell nearly as well as those that are not based on such information, perhaps because claims regarding change and its maintenance are more realistic in the former (Mahoney, 1988). However, as consumers of health care become more sophisticated in their knowledge of available treatments, which this author believes to be a by-product of managed care, the demands to publish SHBs with some empirical support vs. the need to make such books appealing to the general public may become less competing.

6.12.4.3 Technique-focused Self-help Books

A number of very clearly written workbooks on specific techniques for coping with various problems (e.g. tension headaches, depression, anxiety) have been written. Some popular examples are *The anxiety and phobia workbook* (Bourne, 1990) and *The relaxation response* (Benson, 1975), and *Mind over mood* (Greenberger & Padesky, 1995). Although some of the techniques therein have been empirically demonstrated to be effective, especially those in Benson (1975), the use of the books by clients on their own or with minimal therapist contact has not. Perhaps this is partially due to the fact that such books seem most appropriate for use as a supplement to the training of clients in various techniques (e.g., progressive muscle relaxation). Oftentimes, they do not offer an entire treatment plan for addressing all the various aspects of a problem (e.g., behavioral, cognitive, interpersonal), as does a problem-focused book, and may therefore be difficult to assign and test for a particular disorder. However, it is conceivable that their effectiveness in reducing some circumscribed aspect of a disorder (general anxiety or feelings of hopelessness), or in treating subclinical samples, could be empirically tested.

6.12.4.4 Internet Self-help Books

At the time of writing, there are no controlled trials on Internet SHBs. As described earlier, Internet SHBs could greatly expand the number and type of SHBs to be tested. The Internet also adds a new medium to test. For example, the difference between the effectiveness of an SHB that is read in the traditional manner vs. one that is read on the World Wide Web could be illuminating. Internet books have the potential to make SHBs significantly more personalized via their potential to cross-reference a greater amount of information than a traditional SHB (see Dow et al., 1996).

6.12.5 RECOMMENDATIONS FOR FUTURE RESEARCH

It is recommended that statements regarding the effectiveness of SHBs should be made based on a careful investigation of specific types of books separately with more attention paid to the characteristics of individuals who can benefit from them and the experimenters/therapists who utilize them. More controlled trials comparing the effectiveness of the various types of SHBs, especially those in the general, technique, Internet, and other categories would be helpful toward this end. Research on the characteristics of participants, such as reading and grade level, expectations of change, and motivation, should be addressed (Marrs, 1995). The issue of subject selection is also important. Perhaps individuals who typically read SHBs differ substantially from those who do so merely to be in a study for which they will receive some evaluation and/or financial remuneration. Investigations of the difference in outcomes between individuals who are permitted to read and apply the precepts of the book on their own vs. those who have periodic reviews with the experimenter, could be illuminating. Perhaps the use of diary recordings of progress and issues during reading would obviate the need for such frequent contacts with the experimenter. Such frequent contacts may contaminate the findings of self-help research in two important ways: (i) the contact with the therapist, rather than with the SHB, may account for some, if not all, of the improvement noted; and (ii) similarly demand characteristics, rather than the SHB, may elicit some portion of the improvement noted. However, research which compares the effectiveness of psychotherapy, with and without SHBs is not available at this time.

Therapist characteristics which bear on the effectiveness of SHBs, which pertain mostly to the manner in which they are utilized and monitored in treatment (e.g., prescribed vs. suggested, monitored closely or informally), should also be addressed in future research so that practitioners may have guidance on how to make good use of such books. In addition, investigating what aspects of SHBs (e.g., instillation of hope via case examples vs. techniques) account for the most change in clients' behavior, would also be helpful. Both of these issues will be discussed in a later section of this chapter.

In summary, although a carefully selected and closely read SHB, without any assistance from a therapist, may be good enough for some, the available data do not speak to the characteristics of such individuals. Thus, a more conservative approach, one consisting of an SHB plus therapy, may be warranted at this stage, given that the data are not conclusive and the fact that only a small number of SHBs have been empirically validated for use alone. Another reason why this approach might be more advantageous is that readers/clients would have guidance in how to select an SHB and how to adequately adhere to its recommendations. Poor selection and nonadherence are among the most deleterious results of an unstructured approach to self-help (Rosen, 1987). Therefore, because of the tentative nature of the research on SHBs, this author believes that psychotherapy, supplemented by judicious use of SHBs, is a safe and useful alternative to the pure self-help approach. Perhaps future research will explicate further under what conditions this may be the case and under what conditions a pure self-help approach may be indicated. Despite the fact that the prescription of self-help books and other materials is widespread, little research regarding various methods for assigning SHBs to clients or incorporating them into the course of therapy has not been undertaken. Future research should address this and the aforementioned questions as it suggests the possibility of using SHBs to enhance psychotherapy outcomes. It is hoped that the following guidelines for integrating SHBs in the practice of clinical psychology, which have been helpful in this author's work with clients, could facilitate such research.

6.12.6 INTEGRATING SELF-HELP BOOKS INTO THE PROCESS OF PSYCHOTHERAPY

Many studies testing the effectiveness of SHBs do not clearly state how the books are to be used. Some authors, however, have addressed related issues, such as the prescription of SHB (Pardeck, 1990; Starker, 1990); which clients benefit most from a self-help approach (Mahalik & Kivlighan, 1988); and bibliographies of SHBs (Quackenbush, 1991). However, only Pantalon et al. (1995) and Pardeck (1991) have detailed a model of fully integrating SHBs into the course of psychotherapy. A brief overview of the former approach is given below.

6.12.6.1 Selection

Before a therapist can adequately help select the SHB that will be best for a client, it is helpful for him or her to be aware of the most frequently cited positive characteristics of such books. These are: (i) optimistic frame, (ii) encouragement, (iii) advice to seek professional help, (iv) general self-understanding, and (v) understanding about specific problems (Halliday, 1991). This author believes that, in addition to the above, one of the most valued aspects of SHBs is the social validation offered through their suggestion that problems are understandable given life experiences, and that the readers are not to blame. Hence, fear of embarrassment or evaluation by a therapist are nonexistent. Also, instead of a complex diagnosis, the reader is given simple, easy-to-understand explanations for why they are the way they are, via accounts of cases which often mirror their own personal experiences. They also raise motivation to change through examples of others who have succeeded. They typically offer an optimistic outlook on problems and a multitude of suggestions for better coping. In addition, they are perceived by readers to be more efficient than therapy, especially in terms of time, cost, and effort (Starker, 1986).

This author believes that SHBs will be able to offer all of the above, if they are goal-directed and written in a clear and user-friendly format (e.g., tables, figures, charts). They should also offer the reader a multitude of therapeutic exercises with rationales and encouragement, and descriptions of methods to measure noticeable changes (e.g., charts, checklists). In an effort to promote self-acceptance, it should prepare readers for setbacks or failure. In this author's opinion, however, the two most important things an SHB should offer a reader are research-based information and a plethora of case examples of those treated successfully, so that readers can identify with the case examples in a book and be convinced that they have selected an SHB that is appropriate to their needs. Both have also been demonstrated in research to significantly impact on expectancies for therapeutic change (Kazdin & Kranse, 1983). The reader is referred to Pantalon et al. (1995) and Santrock, Minnett, and Campbell (1994) for bibliographies of SHBs recommended for use in the practice of clinical psychology. Seligman's (1994) *What you can change and what you can't* is strongly recommended, as it can help clients, and therapists of any orientation develop realistic expectations for behavior change.

6.12.6.2 When to Use Self-help Books

The second step in integrating SHBs into the course of therapy involves deciding when and why to use them. When clients are experiencing difficulty understanding the nature of the problems they are facing, when the direction therapy should take is somewhat unclear, when clients either resist or have difficulty prioritizing goals, are only some examples of when SHBs can be used. A general rule of thumb, however, is that the use of SHBs could be effective at a point when either or all of these three situations arise:

(i) the client is asking many questions about his or her symptoms or the process of therapy ("How is this going to help me?" or "How do you know this is right for me?");

(ii) the client is resistant in some way and/or does not adhere to therapeutic exercises (e.g., "I can't understand why you want me to do this homework?"); or

(iii) the client appears to be of the belief that he or she is the only person that is attempting to cope with such problems, which may accompany a sense of helplessness (e.g., "No one else has such major problems; I just can't do anything about it").

In these situations, an SHB could bolster the therapist's explanation of a problem, clarify the process of treatment, offer motivation and rationales for doing therapeutic exercises, normalize symptoms, and give hope.

How ready a client is to engage in actual strategies to change behavior may affect how effectively he or she utilizes the advice in a particular type of SHB. For example, if a client is still thinking about whether or not he or she has a problem in the first place or whether he or she believes anything can be done about it, or whether the costs of change are too great, he or she may not be motivated to read a book which offers specific advice regarding how to change behavior directly. Instead they may profit from a book or a section of a book that discusses the pros and cons of their behavior first (e.g., general SHB or the "diagnosis" section of a problem-focused book). This then impacts on what type of book the theorist should assign to the client. One way to assess this is by using one of the various stages of change assessments available which have been shown to correlate with actual attempts to change and which are useful in planning clinical strategies (Prochaska, DiClemente, & Norcross, 1992).

6.12.6.3 Introducing and Assigning Self-help Books

The rationale for asking a client to use an SHB in conjunction with therapy should be planned after the therapist has (i) decided on the target problem; (ii) conceptualized his or her reason for seeking additional materials (e.g., client is asking many questions about the process of therapy); (iii) formulated his or her criteria for selecting an SHB; and (iv) selected an SHB, as well as, the introductory selections he would like the client to read. It may be best not to suggest exercises other than reading for the first two sessions after introducing an SHB, even if the client has already practiced such exercises prior to adding the book. Once all four conditions have been met the therapist can introduce the SHB he or she has selected following the suggestions found in the next several sections.

When introducing the idea of using an SHB to a client, begin with a review of what gains the client has made thus far and how. It is then explained that if these efforts were extended, during nontherapy days and with new exercises, such as with the help of an SHB, greater improvements could be achieved. The client is then asked for his or her thoughts on this. Subsequently, the author shares some of his book selection criteria with the clients and points out the ways that the SHBs generally used by this author are different from other titles (e.g., research-based), many of which their friends may adore. If a client appears motivated to integrate an SHB into the work of therapy, then this author informs the client about the appropriate and reasonable expectations for what can be gained from reading an SHB. The degrees of behavior change and change as a process is emphasized. The client is told that the learning does not necessarily end by the time he or she finishes reading the book, but that it continues and the SHB becomes a reference, which the reader can go back to time and time again. This author then goes through the table of contents of the book with the client, remarking on how each of the sections (preselected by the therapist) is relevant to the client's particular problems and treatment. This exercise is sometimes quite illuminating because it makes it clear how therapist and client conceptualizations of the primary problems or methods of addressing them differ. Therefore, the therapist must be flexible at this early stage and willing to compromise on certain selections or exercises that the client may or may not see as relevant at first. This process of introducing and assigning an SHB also usually helps clients develop their own criteria for future self-help selections made on their own.

This author believes that it is almost always better to prescribe an SHB rather than give the patient a choice of reading it or not. The more confident, directive, and positive a therapist is when assigning an SHB, the better the chance the SHB has of making a therapeutic impact on the client. Therapists should also display high regard for the selected SHB. Therefore, SHBs, and the exercises therein, are almost always assigned as homework, which is monitored by the therapist on a regular basis.

6.12.6.4 Addressing Nonadherence

We have found that it is usually more effective to integrate SHBs into the context of therapy rather than to simply assign them. If they are not an integral part of the therapy, the patients may devalue such books, behavioral homework assignments, and even the therapy itself. If they are not good or relevant enough to use systematically, their use should be seriously questioned. This is true even if a therapist is only using one section of a particular book. However, some patients simply will not comply with such prescriptions as described above and will require more in the way of motivation to actively change problematic behaviors (e.g., a change in type of SHB). Readers of SHBs can mistakenly believe that reading a book, but failing to follow through on specific assignments, constitutes being actively engaged in the changing behavior.

Due to the above, the following suggestions are made for dealing with nonadherence when using an SHB:

(i) self-monitoring, which allows clients to become more aware of their resistant behavior, because a lack of such awareness may be stopping a client from acknowledging the severity of their problem;

(ii) shaping of behavior, which involves positively reinforcing (e.g., giving praise, feedback, or acknowledgment for) each incremental effort toward more compliant behavior;

(iii) agreeing on relevant sections. Frequent reevaluation of therapy goals and objectives facilitates this, and allows for a pace that is comfortable for both;

(iv) assessing therapist demands regarding change. If a therapist is vigilant about monitoring his or her irrational expectations, then the chances of making unrealistic demands of the client, and hence of noncompliance, can be minimized;

(v) anticipating nonadherence, which gives the therapist an early opportunity to plan strategies for addressing this issue. However, it also allows the therapist to view such resistant behavior as part of the process of change, rather than as an annoyance or interference. With this attitude, the therapist can respond to nonadherence in a nondefensive, reflective manner, which can be critical in motivating resistant clients; and

(vi) traditional CBT techniques (e.g., desensitization, cognitive restructuring).

6.12.7 HOW SELF-HELP BOOKS CAN IMPROVE PSYCHOTHERAPY OUTCOMES

Therapists may be able to enhance their effectiveness by adding SHBs to their armamentarium. In general, the manner in which SHBs could do this is by offering to therapists a new medium through which they can motivate behavior change. Specifically, SHBs can:

(i) increase the number and variety of rationales given for treatment interventions, via case examples and interesting anecdotes in understandable language;

(ii) increase opportunities to self-monitor problem behaviors as well as to rehearse adaptive ones, through the many therapeutic exercises they offer;

(iii) enhance adherence to homework by offering the client motivational accounts of other clients and breaking down complex tasks into their component parts;

(iv) increase self-efficacy via a heightened sense that they themselves (rather than the therapist) are solving their problems; and

(v) improve generalization to other settings, because their suggestions are read and implemented in a wide variety of situations outside of the therapy office.

6.12.8 POTENTIAL RISKS AND LIMITATIONS OF SELF-HELP BOOKS

Rosen (1987) suggests that the potential risks associated with the use of SHBs are associated mainly with the misdiagnosis of problems, lack of adherence with procedures, overgeneralized advice, and overstatement of the effects of SHBs. However, this author believes that these risks are associated with the *misuse* of SHBs, rather than by the books themselves. Specifically, SHBs may not help produce positive behavior change when the following conditions exist:

(i) when expectations of change are unrealistic;

(ii) when specific directions are not followed;

(iii) when an irrelevant or inappropriate book is selected (e.g., due to a misunderstanding of the various types of books available);

(iv) when the book selected is not written in terms the reader can understand; or

(v) when it does not match the goals of the reader.

Since the psychotherapy plus SHB approach, described above, addresses each of these conditions, it should help the therapist avoid the potential risks associated with SHBs. Unfortunately, diligent attempts on the part of the therapist to ensure that each of these conditions is met does not always guarantee good outcome with an SHB. One of the most important aspects of using an SHB, as with any problem-focused therapy, is to achieve a good balance between efforts toward change and efforts toward acceptance (Hayes, Jacobson, Follette, & Dougher, 1994; Linehan, 1993). Thus, therapists attempting to integrate an SHB into the course of therapy should remember that at certain points he or she should either put the SHB (e.g., change effort) aside (with the mutual agreement that this is only a temporary change) or change the type of SHB that is being used (e.g., change from a problem-focused to a general SHB, which promotes more self-understanding or acceptance).

One of the fundamental limitations of psychotherapy manuals in general, and SHBs in particular, is the assumption that the same disorder manifested by different people, with different learning histories and contingencies that maintain the symptoms, are to be treated in the same manner. Fishman (1981) refers to this as mistaking "topographical equivalence" for "functional equivalence" (p. 244). In order to treat an individual effectively, the therapist may need to functionally assess each of the client's problematic behaviors so as to fully understand the reinforcement contingencies and how they relate to each problem area. Assuming that the same behavior exhibited by two individuals, compulsions related to unwanted, intrusive thoughts (i.e., topographical equivalence) serves the same function in both (i.e., functional equivalence), such as avoidance of intimate relationships vs. a desire to always be in control of one's thoughts, may lead the therapist to implement minimally helpful interventions. Thus, when using an SHB in therapy, it would be advisable for the therapist to individualize its procedures, either by timing or choosing the interventions or target behaviors in such a way that they are reasonable given the client's entire clinical picture (e.g., symptoms, motivation, social support, family life, occupational functioning, strengths and weaknesses). For example, an empirically validated SHB for generalized anxiety disorder may begin the course of treatment with progressive muscle relaxation, which for some may be anxiety-provoking, rather than relaxing. For such cases, reframing, or more assessment may be indicated. Without a functional analysis of each of this client's problem areas, the therapist might have incorrectly assumed relaxation training to be the best intervention with which to start.

In fact, many of the issues that impinge on the use and effectiveness of manualized treatments in therapy also affect the effectiveness of SHBs. For example, the degree to which therapists individualize such manuals affects clinical outcome, and there is great controversy regarding whether modifications based on clinical intuition or actuarial judgment leads to greater efficacy of the treatment (Wilson, 1997). How a therapist individualizes an SHB for use by a particular client with a unique learning history may impact on its effectiveness in the same way that it does with treatment manuals. However, if future research attempts to experimentally control for differences in administration or individualization, more could be learned about the most productive way to do this. One of the more basic questions would involve a comparison of individualization vs. no individualization, or individualization with and without formal rules, as has been done with standardized treatment manuals. The results of such studies are mixed, but appear to favor actuarial judgment, which would suggest less individualization of standardized books. However, it appears that even those who favor the actuarial side of this debate, suggest that tailoring a treatment manual to reduce disruptive behaviors, and enhance adherence and regard for the interventions (much in the way described above), is both appropriate and improves the effectiveness of the treatment (Eifert, Schulte, Zvolensky, Lejuez, & Lau, 1997; Linehan 1993).

A final purpose SHBs could serve is to further researchers efforts at wide dissemination of research findings regarding empirically supported psychotherapeutiic techniques (Persons, 1997). If SHBs based on empirically validated treatments became as popular to the general public as other books, clinicians who would otherwise be unaware of such treatments might have an incentive to learn and use them (i.e., if individuals in therapy were aware of such approaches, it is conceivable that they would seek such treatment from their therapist).

6.12.9 SUMMARY AND CONCLUSIONS

This chapter reviewed (i) the various types of SHBs available today; (ii) the available empirical studies on the effectiveness of SHBs; (iii) the possible reasons for the appeal of SHBs to the general public and, more recently, to researchers; (iv) an approach for integrating SHBs into the course of psychotherapy, with specific recommendations for selecting, assigning, and using SHBs in the context of a clinical practice; (v) the manner in which SHBs could enhance (a) clinical results, especially via a better understanding of and adherence to psychotherapeutic interventions, generalization, and increased efficiency, as well as (b) dissemination of empirically supported treatments to practitioners and clients alike; and finally (vi) the potential hazards associated with the misuse of SHBs. It was proposed that if therapists used SHBs in the manner outlined, SHBs could be an effective adjunctive treatment in psychotherapy. It is the belief of this author that, with the above issues clarified, future research into the effectiveness of SHBs, including its potential positive impact on psychotherapy outcome, may be more systematically addressed.

ACKNOWLEDGMENT

The author wishes to express his gratitude to Wendy Bobadilla and Beatrice Martineau for their assistance in the preparation of this chapter.

6.13.1 INTRODUCTION

Chapters encouraging the adoption of alternative approaches to service delivery typically combine an overview of intervention strategies with a critical review of evidence for or against each strategy. Such an approach reflects several related assumptions. First, information will increase the acceptance and delivery of the proposed alternative. Second, existing resistance to application of these services reflects a lack of information. Third, information about these has been developed in spite of resistance. Fourth, information developed for strategies which have typically been limited to highly controlled use will be accepted as relevant to the decision to incorporate these approaches into existing service delivery strategies. Finally, with sufficient evidence, the existing service delivery strategies may be replaced by the alternative approaches.

An alternative perspective is that understanding resistance to changing current services and professional definitions is an essential first step to achieving such changes. The transition of mental health from direct to indirect services and from a clinical treatment model to a public health prevention model has been understandably slow and difficult. This chapter reflects the belief that such transitions are necessarily and appropriately slow and that professional resistance is best understood as natural and well-intended rather than as selfish and mean-spirited. Rather than look for enemies to progress, one must understand its impediments and plan accordingly. Such is the focus of this chapter which reviews the history, conceptual, and practical obstacles to the widespread acceptance, development, and implementation of indirect/consultation and preventive approaches by the mental health professions generally and clinical psychology specifically. Rather than attempt to present a compendium of strategies of questionable scientific merit and pragmatically uncertain dissemination, I will examine the circumstances under which progress had developed thus far and propose avenues for accelerating the pace at which further development occurs.

Admittedly, the chapter focuses on the development of these strategies in the US. Systematic descriptions of how these strategies have evolved internationally (e.g., in South America, Australia, and Europe) are being prepared for publication in 1999 and 2000 in the *Journal of Community Psychology*.

In his book, *The creation of settings and the future societies*, Sarason (1972) posits that to understand a human service one must examine the circumstances under which it is developed and delivered. One must particularly appreciate those pre-existing conditions which Sarason (1972, p. 24) labeled as occurring during the period "before the beginning." Change as reflected in an "innovative" service, for example, does not arise without antecedents! Rather, it represents a sequence of events (some of which can be identified and some of which cannot) leading to recognition of the need for change and of the form(s) which that change must take to be accepted and incorporated within the surrounding service structure. As explained in this chapter, such is the case for the growing recognition of preventive interventions as necessary components of a comprehensive mental health and health care strategy. Seemingly, such was also the case for the unfortunate de-emphasis of indirect/consultation strategies following their most recent introduction. At the same time, currently existing and expected conditions are likely to alter the perceived importance of these very strategies.

Originally focused solely on "indirect/consultation strategies," the chapter took an unexpected and fortuitous turn. The invitation to prepare the chapter for this set of volumes came as somewhat of a surprise to the author. Although involved with the development, implementation, and evaluation of community-based mental health interventions for nearly a quarter century, I had not associated my work on the prevention of emotional and behavioral disorders with "indirect/consultative approaches." On reflection, the link is as obvious as it is appropriate. Preventive interventions, by definition, focus on antecedents and concomitants of dysfunction rather than on dysfunction itself. As such, they both represent and rely heavily on indirect means of responding to mental health needs. Conceptually, their influence depends on understanding the nature and dynamic processes among individual and situational factors which are salient to pathogenesis (Lorion, Price, & Eaton, 1989). Pragmatically, the intervention's target is not the pathology but its antecedents, that is, enabling circumstances and related individual diatheses.

A second reason for the surprise was that contemporary interest in consultation and indirect strategies was quite unexpected given the nation's seeming abandonment of both the goals and means of the community mental health movement born in the 1960s. The few remaining vestiges of what was to be a "bold new approach" for responding to the nation's mental health needs seemed doomed in the current environment of managed care, welfare reform, and the search for the origins of emotional and behavioral impairment through neuroscience, genetic mapping, and research on biopsychosocial models of development (e.g., Bronfenbrenner, 1979). Four decades after beginning with lofty goals and expectations, the community mental health center system appears but a skeleton of its former self. Whether even the skeleton will remain in the next decade seems uncertain.

Ironically, what may remain of the "bold new approach" is the seemingly least emphasized and least valued of the five original mandatory services, that is, consultation and education. Again, on reflection, the timeliness of these approaches is understandable. If emotional and behavioral problems are to be economically and efficiently addressed, they must be confronted early and on as many fronts as possible. Consultation and indirect strategies provide potentially cost-effective avenues for encircling situational and systemic elements of dysfunction and thereby the potential for accelerating its amelioration. Less recognized, however, is that these strategies might also contribute to a most timely goal, that is, the actual avoidance of dysfunction. In effect, these strategies represent routes to the prevention of mental disorder and to the promotion of optimal development and improved quality of life.

The latter point highlights a link which has heretofore been largely ignored but which is particularly salient to this chapter. The importance of indirect/consultation approaches was acknowledged nearly four decades ago in President Kennedy's landmark message to the nation calling for a "bold new approach" for responding to mental disorders:

> ... We must seek out the causes of mental illness and mental retardation and eradicate them. Here, more than in any other area, "an ounce of prevention is worth more than a pound or cure." For prevention is far more desirable for all concerned. It is far more economical and far more likely to be successful. Prevention will require both selected specific programs directed especially at known causes, and the general strengthening of our fundamental community, social welfare, and educational programs which can do much to eliminate or correct the harsh environmental conditions which often are associated with mental retardation and mental illness. (Kennedy, 1963, reported in Bloom, 1977, p. 264)

To pursue this goal, "consultation services to other community agencies and mental health information and education" (Bloom, 1977, p. 267) were included as mandatory components of community mental health services. The link between indirect/consultation strategies and preventive interventions was reaffirmed when the editors of this work extended the chapter's focus to include all three strategies.

Confronting the responsibility for designing and delivering a new array of services (i.e., partial hospitalization, emergency, consultation, and education) to heretofore underserved segments (e.g., rural, low-income, or minority) of the population in unfamiliar settings (e.g., in sparsely populated villages, inner-city ghettoes, or working-class neighborhoods), community mental health service providers initially focused on established and evident need rather than incipient or potential disorder (Bloom, 1975; Cowen, 1973). As clinicians they were trained to recognize and treat disorder. Interest in doing these very activities, as professionals, determined, in part at least, their original career choice. Understandably, therefore, their initial forays into consultation and education efforts reflected contemporary assumptions about the nature of disorder and established intervention practices arising from such assumptions.

The implementation of the remaining and predominant mandatory elements of the community mental health movement (i.e., outpatient and inpatient services) focused primarily on pathology as figure and the expert/therapist/provider-serving-the-learner/client/recipient-exchange as ground. Within this framework, consultation and indirect/educational services were designed substantively and procedurally to maximize the recognition of disorder, the efficiency and timeliness of referral for treatment, and the appropriate utilization of community-based resources for supporting the effects of intervention. As explained below, social legislation of the 1960s and 1970s presented significant opportunities for the mental health system and mental health professions to change their conceptions of problems and solutions. Few (e.g., Levine & Perkins, 1997; Mrazek & Haggerty, 1994; Sarason, 1981) believe that the opportunities were taken or their potential fulfilled. Current and anticipated revisions of health and mental health care policies present another chance for substantive change. Whether the outcome will differ remains, for now, uncertain. What is certain, however, is that prior efforts at change were sincere but insufficiently cognizant of how **established** practices, perspectives, and assumptions about the nature of problems and solutions shaped the likelihood of true innovation. As we enter yet another era in which change is seemingly pursued, we must reflect on how current stances will necessarily shape our future.

What seems quite certain is that the potential for change which arose in the 1960s remains unfulfilled! "Community" in the community mental health movement, for example, referred primarily to the recipient and the location of services rather than to the rationale for and procedures of those services (Bloom, 1984). For this and other reasons, the heuristic and programmatic importance of the link between prevention as goal and consultation/indirect strategies as means lost its immediacy. Also clouded was appreciation of the vast array of alternatives which would have become available had the focus been on health and its maintenance rather than on pathology and its treatment or control. Ideally, this chapter will focus attention on the potential of those links and result in a broadening of perspectives as contemporary health and mental health service providers design intervention systems for the future. Toward that goal, it is important to note that the community mental health movement represented a return to rather than discovery of the value of indirect/consultation strategies. That recognition occurred decades before! In fact, the link between indirect strategies and prevention was unquestioned in the early twentieth century!

6.13.2 ANTECEDENTS TO PREVENTIVE CONSULTATION/INDIRECT STRATEGIES

Legislative initiatives have understandably been assigned as much if not more of the credit than scientific findings and professional interest for moving to center stage the mental health disciplines' recognition of and involvement with prevention and indirect/consultation strategies. Attention to indirect/consultation strategies, for example, is assumed to have resulted from passage of the Community Mental Health Center Act (Public Law 88-164) of 1963. Legislative antecedents to that Act included the National Mental Health Act (Public Law 79-487) of 1946. This law was written to facilitate the incorporation of public health principles into the design and delivery of mental health services. It also authorized the establishment of the National Institute of Mental Health which included the prevention of mental disorder among its stated purposes. More than a decade would pass, however, before that goal was publically acknowledged. Nearly two more decades would pass before substantive action was taken to achieve this goal (Goldston, 1986). Nearly 50 years after passage of Public Law 79-487, preventive intervention research remains in the early stages of development and the products of its efforts, although increasing in number and documented value, account for a very small portion of the nation's mental health service effort (Durlak & Wells, 1997; Mrazek & Haggerty, 1994).

Further legislative actions fueled the potential for momentum in establishing and disseminating indirect/consultation strategies. The Mental Health Study Act (Public Law 84-182) of 1955 created the Joint Commission on Mental Illness and Health charged with conducting a thorough and objective study of the human and economic costs of the nation's mental health needs, services, and service delivery systems. The Joint Commission took this assignment seriously. Over five years, it conducted comprehensive studies of topics ranging from the adequacy of staffing resources (Albee, 1959) to public attitudes toward mental health needs and services (Gurin, Veroff, & Feld, 1960) to epidemiological analyses of mental illnesses. In addition to publication of numerous monographs reporting the results of individual studies, the Joint Commission (1961) submitted an integrative summary of its findings and recommendations in its final report entitled *Action for mental health*. That report provided the substantive foundation for the Community Mental Health Centers Act of 1963.

The Joint Commission's report was supported by two significant epidemiological studies (Hollingshead & Redlich, 1958; Srole, Langner, Michael, Opler, & Rennie, 1962) published during that period. Whether measured in terms of need or demand for services, a serious imbalance was evident between the availability of mental health services and the prevalence of mental disorder in adults. A subsequent epidemiological study confirmed the existence of at least an equivalent imbalance between children's needs and available services (Glidewell & Swallow, 1969). These and related studies provided what appeared to be convincing support of "Albee's (1959) pessimistic assessment that sufficient mental health staffing resources would *never* be available to treat those in need within the dominant individual service delivery models.

Other sources of personnel (e.g., paraprofessionals, Durlak, 1979, and "natural care givers," Cowen, 1982) and other models of service (e.g., empowerment strategies, Rappaport, 1977) if developed and supported offered routes to redressing these imbalances. The founders of the emerging field of community psychology and their followers devoted considerable effort to pursuing such alternatives (Cowen, Gardner, & Zax, 1967; Iscoe, Bloom, & Spielberger, 1977). Although overlapping in terms of their goals and objectives, community psychology (e.g., Heller, Price, Reinharz, Riger, & Wandersman, 1984; Rappaport, 1977) and community mental health (Bloom, 1984) took somewhat differing routes to finding alternative solutions to resolving the needs/services imbalance. Each, however, emphasized the development and dissemination of preventive interventions and indirect/consultation strategies as outcomes to be achieved. Each spoke of the value of expanding definitions of providers of service, of the timing of services, and of the nature of services (Riessman, 1965). Both community psychology and community mental health, however, retained a strong identification with clinical psychology. With notably few exceptions (Iscoe et al., 1977; Phares & Trull, 1997), doctoral programs in these emerging fields devoted far more time to training in traditional theories of pathology and traditional methods of diagnosis and treatment than in those uniquely distinct theories and methods focused on communities. Understandably, professional identification was more likely to default to clinical than community psychology.

Simultaneously, prevention's advocates reminded policymakers of the public health maxim that no disease or disorder had ever been controlled by treatment but only by prevention. As early as 1962, the American Public Health Association identified six categories of mental disorder which, because their etiology was known, were preventable (Bloom, 1984). These categories included diseases caused by: (i) poisons (e.g., brain syndromes following exposure to solvents); (ii) infections (e.g., rubella); (iii) genetic disorders (e.g., TAY-SACHS disease); (iv) nutritional deficiencies (e.g., pellagra); (v) injuries (e.g., traumatic head injuries); and (vi) general systemic disease (e.g., prematurity). It is important, however, to note that early in the development of the community mental health movement, prevention represented not simply an idea but also an attainable goal. Moreover, guidelines for shifting to alternative approaches were provided by Caplan in his influential works, *Principles of preventive psychiatry* (1964) and *The theory and practice of mental health consultation* (1970). Riessman (1965) among others (e.g., Fairweather, Sanders, Maynard, & Cressler, 1969) described innovative ways in which self-help and environmental change, alone or in combination, offered relief which could precede and potentially avoid dysfunction and exacerbation of existing problems. These efforts did not depend on professional resources to operate and, under appropriate circumstances, may have become self-sustaining.

Yet the solution to a problem is determined in large part by how it is defined and how it is presumed to have arisen. As noted, the movement toward community-based service delivery occurred at a time that conceptions of health and especially pathology were focused primarily on *internal individual* states (Sarason, 1981). Changes in the individual's affective response to stress, behavioral response to external stimuli, and the capacity to alter those responses were assumed to occur through interventions targeted to individuals. From that perspective, a reasonable response to Albee's (1959) prediction of chronic shortages in mental health professionals capable of delivering individual services was to resolve that shortage by increasing the nation's capacity to train such professionals. Concurrent with legislation to incorporate public health concepts into mental health theory and practice and to establish the community mental health movement, Congress funded programs to train substantial numbers of mental health professionals to provide traditional diagnostic and therapeutic services (Phares & Trull, 1997). The inclusion of reimbursement for mental health services in health care policies and the growing public acceptance of outpatient mental health services led, in psychology, to a proliferation of university and nonuniversity-based programs for health service providers (Phares & Trull, 1997). The shortages in mental health professionals capable of serving individual needs predicted by Albee (1959) appears to have been substantially resolved, if not replaced by a surplus (Routh, 1998).

The surplus becomes undeniable if subdoctoral providers in psychology, counselor education, marital and family practice, counselor education, nursing, and social work are included in service delivery resources.

Ignored in this solution were the alternatives suggested by Albee (1959) and echoed in the Community Mental Centers Act, that is, to expand the range of personnel available to provide services and to expand the range and nature of those services. Indirect/consultation efforts targeted at other than the detection of those in need of referral for treatment or the enhancement of nonmental health service providers (e.g., teachers, social service case workers) to support mental health interventions could not be justified within the prevailing understandings of pathogenesis, dysfunction, and treatment. Similarly, efforts to establish the feasibility of responding to mental health needs using providers who were indigenous to the communities in which the problems arose (e.g., Sobey, 1970) may have demonstrated their effectiveness (e.g., Dawes, 1994; Durlak, 1979) but the weight of evidence was insufficient to topple the individual focus and internal emphases dominant at the time.

Being from the neighborhood, for example, could only be of advantage to a service provider if characteristics of the neighborhood were assumed to contribute to the etiology, maintenance, and resolution of emotional and behavioral dysfunction. If one assumed otherwise, one would reasonably question the therapeutic benefit of attracting and retaining heretofore untreated segments of the population if the insights needed for symptom removal could not be achieved in the presence of an "unqualified therapist." Those who challenged the innovativeness of the community movement pointed to its seeming lack of theory and focus. Levine and Perkins (1997) describe reactions to the community mental health movement as follows:

> The new thrust went off in all directions at once, with little coherence and little conceptual clarity.

> Critics committed to traditional medical model practice looked askance at social activism. Those committed to "intrapsychic supremacy " (Levine, 1969)—the belief that problems in living result from people's internal psychological structures, which in turn dictate perceptions, feelings, and actions in everyday situations—viewed the activists as misguided romantics who had foolishly strayed from proper professional roles and activities. Community-oriented critics of traditional practice were equally firm in their convictions but had little to offer by way of alternate conceptualizations. (pp. 59–60)

Alternative perspectives had yet another chance to establish themselves as a viable element of federal health care policies. Shortly after his election, President Carter created the President's Commission on Mental Health to review the state of the nation's needs and response capacity. In essence, the Commission's numerous task forces and panels revisited the issues raised by President Kennedy's group and recommended continued and vigorous pursuit of many of its most innovative elements. The Commission's findings were translated into the Mental Health Systems Act (Public Law 96-398). Included within this legislation was the requirement that the National Institute of Mental Health establish an administrative unit focused on funding, evaluating, and disseminating preventive interventions. The prevention of emotional and behavioral disorders was to become a central and adequately supported element of the nation's mental health policy (Bloom, 1984). Significant changes in service and training priorities were expected along with consequent shifts in the balance of direct and indirect approaches to serving the nation's mental health needs. Just as suddenly, the Mental Health Systems Act was repealed! Newly elected President Reagan's initial budget shifted to the states responsibility for deciding which services to provide with the federal government's newly designed block-grant funding approach to underwriting the costs of such services. If they were to be funded, the preventive and indirect services needed to compete for limited funds which were primarily used to support the provision of direct services to those with established diagnosed needs. Unfortunately, the promises of benefits to be gained from support for preventive interventions significantly exceeded the evidence of such benefits (Lorion et al., 1989; Mrazek & Haggerty, 1994) and left the field open to significant challenge (Albee, 1986). Ironically, an appreciation of the history of mental health strategies would have revealed that justification for these alternative services could be found in the efforts of mental health providers decades earlier.

6.13.3 BEFORE THE BEGINNING; RETRACING PAST STEPS

Examination of the scientific and legislative accomplishments reviewed thus far might lead one to conclude erroneously that prevention and indirect/consultation strategies were neither recognized nor attempted before the latter half of the twentieth century. The legislative initiatives and epidemiological studies just described, however, were not mental health's initial foray into indirect/consultation and preventive strategies. Human services generally and the mental health services specifically have not only applied such strategies throughout the twentieth century but periodically such strategies represented a dominant and explicit objective. Considered in their entirety, it appears quite possible that indirect/consultative approaches and even preventive interventions may have both a longer and a more successful history than interventions which provide direct services to individuals.

In their analysis of the history of consultation, for example, Mannino and Shore (1986) report that clinical psychology has been associated with such interventions since its inception. Long identified as a defining milestone of clinical psychology's formation as a profession, the establishment of Lightner Witmer's psychological services clinic at the University of Pennsylvania in 1896 is also quite relevant to this chapter. Reportedly, this clinic's services documented early professional appreciation of the value of indirect services and of both the desirability and feasibility of balancing attention to referred needs with creation of ways to avoid such needs (Mannino & Shore, 1986). Little known is the fact that Witmer's clinic relied on consultative interventions to deliver a substantial portion of its services. Comprehensive assessments of the nature and origins of children's cognitive, behavioral, and impulse control problems were, for example, as likely to result in interventions with the child's family or school as with the child. Frequently, analysis of the needs of a referred child included diagnostic assessments of instructional procedures. In turn, the intervention often involved prescriptive changes in school curriculum and detailed suggestions to teachers for handling disruptive behavior within the classroom setting.

Established during the initial decade of the twentieth century to respond to the needs of immigrants and low-income families, the Settlement House Movement hired teachers to visit the schools enrolling the children of families served by the Movement. These itinerant teachers would observe classroom procedures and recommend changes in curriculum, classroom organization, and instructional methods to improve children's educational performance. Such visits were intended both to reduce the needs of identified children and to enhance the overall effectiveness of the classroom. Without being labeled as such, these visits represent very early attempts to prevent emotional and behavioral problems and to promote optimal development and adaptive functioning.

In the 1920s, similar goals were pursued by the Child Guidance Movement. Healy's Juvenile Psychopathic Institute in Chicago, for example, developed and implemented programs to assist troubled youth by enhancing the capacity of relevant community agencies, including the schools, to serve the needs of referred and nonreferred youth. Healy's staff also worked to increase public understanding of mental health principles and public acceptance of emotional problems. The recipients of these educational programs were the communities in which the youth lived and the public agencies which served them. Child Guidance staff in other cities established service priorities for a community based on systematic assessments of local needs and resources. Findings from this planning step identified gaps in services and achievable objectives. Problem solutions often included programs to educate staff from relevant agencies about mental health principles and strategies.

Child Guidance staff also worked to improve a community's readiness to develop its own child guidance capacity. As described by Mannino and Shore (1986), such capacity development activities included the aforementioned local assessments as well as field services which carried out site visits, assisted existing service organizations to recognize the contributions of other human services, and identified ways for these organizations to network and collaborate. Through their activities, child guidance workers sought to make explicit the close relationship between the child and family as case and the community in which services were provided. Aware of the futility of attempting to respond individually to each case, child guidance workers often chose instead to alter the settings (e.g., home, school) in which the child lived and learned by influencing the decisions made by teachers, parents, and other caretakers. To effect such changes, caretakers were provided information about human development and child care methods. Child guidance workers explained these principles and provided direct models of alternative parenting or teaching behaviors. Child guidance workers recognized that their consultative and educational services should not be designed to make their recipients into mental health workers but rather to improve their functioning as parents or teachers. When the recipient was a service organization, the goal was not to change it into a mental health agency but to improve the developmental sensitivity, efficiency, and effectiveness of its intended services.

Reflecting on these approaches, it becomes apparent that attention to indirect/consultation strategies preceded by several decades the community mental health movement. Lessons reflected in these services included appreciation of the need to understand, value, and respect the perspectives and skills of a variety of service organizations. Movements developed at the turn of the twentieth century (e.g., Child Guidance, Settlement Houses, Mental Hygiene) appreciated the significant problems in adjustment confronting families attempting to cope with immigration, emigration, and poverty. Neither the families nor the organizations associated with these movements had adequate resources; both confronted challenging and unforgiving circumstances. Early on, the movements recognized that attempting to solve problems individually could not succeed. With their limited financial and staff resources, they focused on reducing the demanding quality of the environment, on enhancing the responsiveness of existing organizations, and the benefits of interorganizational collaboration and (long before the term was popular) on empowering parents, teachers, and citizens to respond to needs confronting them.

6.13.4 THE COMMUNITY MENTAL HEALTH MOVEMENT: A LOST OPPORTUNITY

As noted, following an intensive study of the nation's mental health needs and resources, the Joint Commission on Mental Health and Illness concluded that a "bold new approach" was needed if services were to respond to need (Joint Commission on Mental Health and Illness, 1961). The Joint Commission's report urged the nation to pursue alternatives to a mental health delivery system which was recognized as unavailable, inaccessible, and unacceptable to significant portions of the population (Joint Commission on Mental Health and Illness, 1961). Then as now, the need for responsiveness and relevance mandated the development of strategies which fit the actual circumstances within which people lived, learned, worked, and recreated. Then as now, the need to respond early rather than later was perceived as both economically responsible and humane. Then as now, responsibility for the emotional and behavioral health of individuals extended beyond the mental health professions. As reported by Gurin et al. (1960), physicians and the clergy were considerably more likely than psychologists, psychiatrists, or social workers to be approached for help with emotional problems. Subsequently, Cowen (1982) noted that hairdressers, bartenders, retired persons, and many others in the community served or could serve as valuable resources for those experiencing emotional discomfort.

What in the past may have been defined as "simply being a good neighbor" has the potential of being organized into a pervasive network of support for those suffering distress which can be tapped naturally without risking the personal and public stigma of mental health diagnosis and treatment. Many forms of indirect/consultation approaches are, in fact, designed to sensitize others to the responsibility and ease of "simply being a good neighbor" and to facilitate their capacity to fulfill it. Regrettably, these approaches received far too little attention to flourish during and since the 1960s. In fact, few "bold new approaches" were developed which redefined the timing and nature of mental health interventions. The question presented in this chapter is: "will the potential of indirect/consultation be recognized and exploited now and in the decades to come?"

One by one, whether labeled client, patient, or consultee, those presenting emotional and behavioral dysfunction have been approached by growing legions of mental health service providers. The sincere and somewhat effective efforts of these providers have not, however, stemmed the tide. As reported in Rouse (1995), the proportion of the nation's citizens suffering from emotional and behavioral (including substance abuse) disorders remains unacceptably high. Nor is there any basis for anticipating this tide to abate in the foreseeable future. Whatever their modality, direct approaches are limited in this regard by their focus on the individual and by the requirement that pathology must be present or imminent before intervention can take place.

In his pointedly titled book, *The absurd healer*, Dumont (1968) foresaw this outcome as the community mental health movement was just beginning. A decade later, I experienced Dumont's insightful moment as I entered the waiting room of a public clinic. I was then part of a team of mental health professionals excited by the opportunity to develop a short-term therapy program for indigent clients. We seemed to be a success! Clients were referred in substantial numbers; most cooperated with treatment protocols and participated in the 8–10 session program. We gloated to colleagues when an attempted comparison with long-term protocols could not be completed because few of the long-term clients attended the minimum of four sessions required for inclusion in the study. For a moment after I entered on this day, the waiting room full of therapy clients confirmed my certainty that our protocol represented a solution to the unacceptable levels of measured pathology in low-income populations (Lorion, 1973, 1974).

Suddenly, I realized that however successful we were, the room would never empty! Clients would come and go; their improvement ranging from considerable to none. Yet, without a substantive change in the system of care, others would always take the place of those who left. This prediction appeared valid whether long- or short-term interventions were provided and whether the recipients were individuals, groups, or families. To empty the waiting room, I and my colleagues would have to change our sense of when, where, and how we intervened. We would also have to shift our definition of the problem and of our responsibility for its solution from the waiting room to the circumstances and conditions which led to its need. We would, in effect, have to shift our existing theories of how problems arose and our theories of their solutions. Such shifts presented enormous challenges to a system seemingly committed to change. As noted, our profession has yet to commit wholeheartedly to confronting those challenges!

6.13.4.1 Shifting One's Conceptual Frame

With hindsight, it seems difficult to understand the mental health fields' reluctance to adopt wholeheartedly the flexibility and potential breadth of effect associated with applying indirect/consultation strategies in the pursuit of preventing mental illness and responding to emotional disorders. Passage of the Community Mental Health Center's Act provided the political support and financial backing seemingly necessary for shifting from an emphasis on treatment to understanding and ultimately controlling factors relevant to the development and maintenance of disorder. Bloom's (1977) analysis of this "bold new approach" makes evident that talented, dedicated, and hard working individuals were committed to its development. Soon after passage of this landmark legislation, the Swampscott Conference laid the foundation for the field of community psychology (Bennett et al., 1966). Subsequent organizational meetings of this group (e.g., Iscoe et al., 1977) gave evidence that this emerging field had momentum as reflected in budding programs of research, the development of programs at the master's and doctoral levels, and a growing corps of adherents anxious to enlist in this movement. Voicing a commitment to the integration of science and practice, this emerging field's established leaders led the way for successive generations to establish a critical mass of providers of indirect/consultation and preventive interventions (Iscoe et al., 1977).

Within a decade of its inception, community psychology appeared to have the commitment, momentum, and tools to move mental health toward acceptance of conceptions of etiology that extended beyond the individual and conceptions of intervention that redefined service delivery in partnership (Tyler, Pargament, & Gatz, 1983) rather than caretaker roles (e.g., Heller & Monahan, 1977; Levine & Perkins, 1997; Rappaport, 1977). After a decade of building a foundation for a national program of prevention work (Klein & Goldston, 1977), this perspective shift appeared to have taken root and become ready to blossom. For the next decade, leading advocates of prevention science, policy, and practice met regularly at the Vermont Conference on the Primary Prevention of Psychopathology (Kessler & Goldston, 1986). Funding for research on the prevention of emotional and addictive disorders began to rise with passage of the Community Mental Health Centers Act in 1963, a trend which has generally continued to the present (Mrazek & Haggerty, 1994).

Yet, three decades after passage of the Community Mental Health Centers Act and five decades after formation of the National Institute of Mental Health with its mandate to bring public health principles to mental health care, the mental health fields remain at best ambivalent toward and distant from prevention as a goal and indirect/consultation strategies as means to that goal. Proposing recommitment to that goal or attempting to convince readers that recent scientific findings argue convincingly that it lies within reach seem quite unlikely to have other than limited success. Rather, it seems important to examine the mental health field's seeming resistance to what all agree is a desirable outcome, that is, the avoidance of disorder and the promotion of positive mental health. Levine and Perkins (1997) raise a plausible explanation, that is, those proposing the shift from treatment to prevention and from direct to indirect/consultation services "had little to offer by way of alternate theoretical conceptualizations" (p. 60).

Other explanations seem rather less easily supported. Resistance to changing mental health's goals and methods must be considered historically. As reported in Mannino and Shore's (1986) review and echoed in Sarason's autobiography (1988), we have been there before! Attempts to develop and disseminate indirect strategies early in the twentieth century make evident that their limited survival cannot be attributed to a lack of talent in its advocates, a lack of social support for the resulting programs, or even a lack of evidence of their contribution to the welfare of those served. It is seemingly not about the creativity of those who design interventions, the importance of the research questions raised, the social problems addressed, or the explanatory power of the methods used to find answers (Sarason, 1996).

Having devoted much of his career to understanding the intractability of educational methods to genuine change, Sarason (1990, 1993) warns against attempts to understand the intransigence of existing approaches by finding and blaming those who oppose change. He notes:

> Our task would be incomparably easier if such villains existed. Being imprisoned in tradition, being resistant to and fearful of anything other than superficial change and window dressing, puzzled by the failure of past efforts, allergic to fads and fashions, disenchanted with quick fixes—such attitudes and reactions are not those of villains. (Sarason, 1993, p.13)

Subsequent comments about impediments to educational change seem equally applicable to understanding the pace at which indirect/consultation and preventive approaches have been adopted by the mental health fields:

> If everyone is in agreement that we are faced with a set of problems that we have to do something about, and if in the post-World War II era serious people have committed themselves to valiant efforts at reform, why have the results been either so modest, minuscule, or nonexistent? That was the question the book (Sarason, 1990) tried to illuminate. It was not about what to do; it was about how we have been thinking, what axioms we have unreflectively accepted as right, natural, and proper, and alternative ways we should begin think. (Sarason, 1993, p. 13)

Sarason explains that existing conceptions of how emotional and behavior disorder developed and needed to be remedied were reflected in priorities for research and interventions. Assuming that the seeds of pathology lay within the individual leads to the conclusion that changes in the individual are necessary to correct disorder. That perspective was dominant before, during, and after earlier attempts to shift from direct to indirect approaches and was reinforced by clinical psychology's acceptance of psychiatry and medicine as the definers of the nature of problems and solutions (Phares & Trull, 1997; Sarason, 1981, 1985).

Reluctance to shift to the public health perspective are understandable. Public health practitioners traditionally have viewed disease and disorder as the consequence of complex relationships between individual vulnerabilities (i.e., diatheses) and situational factors (i.e., stress) and of interventions (especially those seeking to prevent disorder) as requiring an understanding and alteration of aspects of the host (i.e., the individual presenting the disorder), the agent (i.e., the cause of the disorder), or of the environment (i.e., of the circumstances which bring the host in contact with the agent) (Lilienfeld & Lilienfeld, 1980). Ideally, at least a portion of the contributions of each element of this classic public health triad (i.e., host, agent, environment) will be understood in planning the preventive intervention. That understanding will identify those points along the etiological chain vulnerable to intervention and thus opportunities for avoiding or interrupting the pathogenic process.

The public health perspective challenges many core elements of clinical psychology's most influential theories, research methods, and concerns (e.g., to understand, predict, and control individual differences). Not surprisingly, clinicians tend to focus their research and services at the individual level. By contrast, public health interventions target populations or segments thereof and measure their impacts at the population rather than individual level. Of concern to proponents of indirect/consultation and preventive approaches is the seeming reluctance of psychology's community-oriented fields to emphasize public health rather than traditional clinical orientations. This individual orientation is confirmed in examinations of the content and methods of published community psychology research in its initial decades (Lounsbury, Cook, Leader, & Mears, 1985) and thereafter (Heller, 1989; Levine & Perkins, 1997). Community psychology's endorsement of the prevention of disorder and the development and adoption of interventions to change social policies and resolve social inequities as defining goals are slowly translating into substantial research and programmatic activity beyond the individual level of analysis or impact.

Echoing Sarason (1993), I would assert that the villains who are obstructing our pursuit of innovation and appreciation of indirect/consultation and preventive approaches are not "them"; contrary to Pogo, nor are they us! The impediment is the difficulty of leaving the traditions and methods of clinical training when such training is valued both within an existing professional culture and within the larger society. Sarason (1993) argues that "if we have learned anything with near certainty, both from the organizational and psychotherapeutic literature, it is that those who seek to change find themselves at some point resisting change" (p. 28). His perceptions about the difficulty of creating new forms of service settings seem to apply equally to the creation of alternative services. Resistance to change must be recognized and expected as part of the process of change which must be thoughtfully and sensitively countered rather than simply regretted or condemned. Regarding the introduction of innovative settings, Sarason appreciated that "if there was anything about which we were truly secure on the basis of past experience, it was that we were embarking on a venture that was very complicated, guaranteed to arouse anxiety and doubt, and, in all respects a venture that could bring out the best and worst in us" (Sarason, Zitnay, & Grossman, 1970, p. 71). Reflecting on the fate of indirect/consultation and preventive approaches thus far, one might apply the same lesson.

Moving from an individual-clinical to a public health perspective required abandoning what was known and valued by the profession and, admittedly, reimbursed by society. As noted, the design, development, and delivery of public health interventions ran (and continues to run) counter to many aspects of clinical training. Many indirect/consultation and preventive interventions are intended to preclude either the need for clinical intervention or for professional intervention. In either case, clinical involvement in mental health service delivery would be reduced. The fact that, once established, the majority of public health interventions would not even belong to us raises yet another impediment to shifting from clinical to public health perspectives. Few professionals readily accede to such generosity! More likely we are influenced by "professional preciousness," that is,

> the tendency of ... professionals to view their technical skills in very precious kinds of ways, that is, to overestimate the differences in skills among the professions and to underestimate the communalities ... . Each field does have a core of distinctiveness, and thus should be both recognized and treasured. It is one thing, however, to say that each field has a distinctive core of skills and it is quite another thing to say that *everything* a particular profession does is either distinctive or not, in part at least, learnable by the other professions in the settings in which they work together. (Sarason, Levine, Goldenberg, Cherlin, & Bennett, 1966, p. 587)

If this applies to our dealings with other professions, one can only assume it is not diminished when those with whom we are to share, if not turn over entirely, our clinical and intervention skills are nonprofessionals.

Consultants, after all, teach elements of their expertise to others so that those others can apply the elements. Health promotion and disease/disorder prevention involves us with segments of the population to which we cannot lay claim based on our expertise in the diagnosis and treatment of psychopathology. Without an accepted taxonomy of health, we cannot use a specialized lexicon to stake out that claim. Indirect strategies which require entry into the realm of public policy, system analysis, and institutional change frequently requires that we do so without a recognized credential which asserts *prima facie* that such involvement is both our right and responsibility. Indirect/consultation and prevention strategies demand that we operate within alien territory in which generic knowledge and skills are the currency for goal attainment. Encouraging people in need to take advantage of self-help groups, enabling those without such experience to recognize and assert their right to influence the allocation of resources, and applying our science and profession to make teachers, parents and social service providers better at what **they** do seem quite discordant with established definitions of professional functioning.

In the sole course on consultation I encountered in graduate school nearly three decades ago (during community psychology's presumed take-off phase), I was both impressed and frightened to learn that effective consultation is documented by evidence that the service is no longer needed by its recipient. It seemed that the task required providing recipients of the services with possession of critical elements of what I offered to be shaped in whatever form **they** deemed useful. My job, in effect, was to make my job unnecessary! Providing prevention and indirect/consultation services seemed to require literal acceptance of Miller's (1969) mandate that we "give psychology away." It simultaneously challenged the content of most of my didactic and clinical courses! It turned around basic assumptions about professional responsibility, and about the patient's capacity to change their problem behaviors and feelings. Most importantly, perhaps, it required significant revision in the very understanding I was developing of why people behave and feel as they do.

6.13.4.2 Shifting Emphasis from Inside to Outside

Suppose that the emotions and behaviors which concern mental health professionals reflect not only internal processes but also the circumstances under which they are displayed? Were this the case, to what should one attend . . . the people or the circumstances? Three decades ago, as the Community Mental Health Movement was getting underway, Barker (1968) and his colleagues proposed that **behavior settings** have greater influence on the expression of certain behaviors than the people who inhabit those settings. In other words, one might predict what will happen if one knows **where** it is expected to happen more so than if one knows **who** will be present. If generalizable, this assumption implies that understanding the conditions under which social services are provided, classroom instruction is given, play is attempted, or employment opportunities arise may predict expressed emotion and behavior better than (or if combined with) information about the individual's early childhood experiences, measured intelligence, or personality profile. It also implies that structuring those conditions might influence predictably the experience and expression of emotions and behaviors. Such a perspective would provide a theoretical rationale for program, setting, or system consultation focusing on the conditions under which people lived, worked, played, and learned. Although given little attention, a substantial theoretical and empirical basis for responding to individual emotional and behavioral needs through indirect/consultation approaches has been developing for decades.

It should be noted that attributions to factors external to the individual have a long and respected history in public health. The classic "host–agent–environment" model for understanding the occurrence of disease has successfully informed efforts to prevent and control threats to physical health. It worked because it looked both **within and outside** the individual to understand vulnerability and resistance to disease. Consideration of individual and environmental factors allows for the design and implementation of interventions whose health promotion or disease/disorder prevention effects can be delivered unobtrusively. To be effective, it is not necessary that the recipients of these interventions be either identified or participate actively. Rather, not unlike fluoride in the water or guard rails along the highway, the environment can be changed in ways which are preventive and health promotive. Many of these interventions operate without professional involvement and independent of either the cooperation or knowledge of the vulnerable individual. By contrast, the application and ultimate success of treatment generally depend on multiple patient variables including acknowledging the need for, having access to, being able to pay for (in terms of money and time), and complying with a treatment protocol. Interventions which have their effects independent of such factors and, ideally, which preclude the need for treatment would clearly be logistically and humanly advantageous. To consider those as viable, however, one must believe that factors **external to the individual** are salient to health and illness.

In the early eighteenth century before germ theory accounted for contagion, the spread of disease among the poor was attributed to "miasma" (i.e., bad air). As Bloom explained (1977):

> Miasma theory held that soil polluted with waste products of any kind gave off a "miasma" into the air, which caused many major infectious diseases of the day. People living near swamps, and thus particularly vulnerable to marsh gases, were thought to develop fever from these gases—a fever that came to be known as *malaria* (bad air). The miasmist felt that the way to prevent disease was to modify the environment—to remove the sources of the miasma. (p. 71)

Given confirmation that a different external factor,"germs" (i.e., viruses and bacteria) explained most infectious disorders, miasma theory had limited influence on public health policy and practice. Its major tenet, however, informs concepts of vulnerability and resistance to emotional and behavioral disorders.

Miasma theory posits that nonspecific characteristics of an environment are pathogenic. This position echoes widespread beliefs among mental health epidemiologists (e.g., Dohrenwend, B. P. & Dohrenwend, B.S., 1981; Dohrenwend, B. S. & Dohrenwend, B. P., 1981; Dohrenwend et al., 1987) that elements of the environment linked to experienced stress are significant pathogens. Analogously, it echoes explanations of delinquency based on social learning and modeling processes (Berkowitz, 1993; Goldstein & Keller, 1987) and links observed among neighborhood disorganization, deterioration (e.g., the presence of broken windows and littered vacant lots), and antisocial acts (Gold, 1987; Levine & Rosich, 1996). Continuing the analogy, indirect/consultation strategies could be thought of as avenues to "modify the environment—to remove the sources of the miasma" (Bloom, 1977, p. 71).

6.13.5 EXTERNALIZING THE STUDY OF BEHAVIOR

Albeit outdated and dismissed, miasma theory is offered to focus readers' attention on nonspecific characteristics of settings and situations in which disease and dysfunction disproportionately occur. Alternatives to miasma were sought because of the variability of its effects, that is, not all exposed became ill. Not understood at the time were how individual characteristics enhanced resistance or raised vulnerability. Such distinctions are central to contemporary diathesis-stress models of illness (Lilienfeld & Lilienfeld, 1980). The complexity of understanding how nonspecific setting factors mix with individual variability raises questions about the processes by which each influences the other. More than six decades ago, Lewin (1935) asserted the importance of contextual factors in his widely cited formula:

$$B = f(P, E)$$

This formula reflects Lewin's (1944) concept of "psychological ecology," that is, consideration of setting characteristics and opportunities *and* individual characteristics and constraints into predictions of human behavior. Lewin's perspective has been studied along the lines of research emphasizing, respectively, **transactional** (i.e., the person in environment) and **environmental** contributions to behavioral and developmental processes. The distinction between the two lines of inquiry is one of relative rather than absolute emphases of the contributions of individual and situational factors in determining behavior. Both lines provide important scientific and clinical bases for the design and evaluation of indirect/consultation strategies and offer avenues for altering pathogenic processes toward preventive goals.

The qualifier,"transactional," represents an important element of Lewin's conceptualization of behavioral dynamics. A transaction refers to the inter-relational processes between individual and situational factors in which each reciprocally influences the other. The distinction between a "transaction" and an "interaction" lies in the former's bidirectional nature, that is, each component in the transaction influences the **successive** states of the other. Dewey and Bentley (1949) described transactional processes as a basis for epistemological analysis. Based on the models of thought articulated in that work, the study of human behavior requires consideration of the actor (i.e., the knower), that which is acted upon (i.e., the known), and the circumstances under which the action occurred (i.e., the situation in which the knower confronts the known). It is within that entirety that the meaning of an action or event must be understood. As explained by Allport (1955):

> Perceptual order and stability can be regarded not merely as a matter of the appraisal of cues, but also as a more dynamic relationship between the organism and the environment. When percepts

> are attained their attainment is likely to involve direct participation in some process of overt adjustment. *Perception and action can be seen to have a close functional relationship* (emphasis added). (pp. 271–272)

From a transactional perspective, violent acts occurring in a school, for example, would be understood in terms of when, how, and where they occur, who is present at the time, and how each person present interprets the events and the options available to respond to those events. The coalescence of those elements gives meaning to the violence and determines how its occurrence influences subsequent events. Among those events are the responses of others to the violence, the likelihood of its continuation by its perpetrator(s), and of its adoption by others (Lorion, Brodsky, & Cooley-Quille, 1998).

As used in this chapter,"environmental" research refers to studies which examine the contributions of setting characteristics to behavior. As explained by Schoggen (1989), environmental studies are exemplified by analyses of the physical or built environment on behavior (e.g., the design of playgrounds on student interactions or of classrooms on reading) and of physical qualities of a setting on functioning (e.g., noise and lighting levels on classroom on-task behavior). Such studies may, however, focus on the "the ecological environment (which) includes also the objectively observable *standing patterns of behavior* of people—that is, specific sequences of people's behavior that regularly occur within particular settings" (Schoggen, 1989, p.2). This subset of environmental studies must, themselves, be distinguished from work on the "psychological environment," that is,"the subjective representation of the objective environment by a given person at a particular time" (Schoggen, 1989, p. 3).

6.13.6 ENVIRONMENTAL MODELS OF BEHAVIOR

As noted, Lewin's (1935, 1944) assertion that behavior is a function of person and environment stimulated inquiry into the contribution of setting characteristics in shaping behavior. Barker, a colleague of Lewin, developed this line of research. In Barker's (1968; updated in Schoggen, 1989) view, the distinction between Lewin's concept of "life-space" or the psychological environment (i.e., the world as an individual *perceives* and is affected by it) and the ecological environment (i.e., the objective characteristics of real-life settings) makes evident the need to understand how the physical properties of settings, including the objects within them and the shared rules for relating to them, influence behavior.

Support for the importance of attending to the ecological environment was provided in the findings of a series of early studies (summarized in Barker, 1968) on children's behavior across school settings. Barker and his colleagues determined that knowledge of situational characteristics of such settings resulted in better prediction of children's behavior than knowledge of the characteristics of individual children. Across a number of settings, children acted more like each other within a given setting than like themselves across settings. To the researchers, measurable properties of settings appeared to constrain the range of alternative responses and opportunities for behavior within each setting.

Barker and his colleagues used the concept of "behavior settings" to describe such person-setting linkages. As explained by Barker:

> A behavior setting has both structural and dynamic attributes. On the structural side, a behavior setting consists of one or more standing patterns of behavior-and-milieu, with the milieu circumjacent and synomorphic to the behavior. On the dynamic side, the behavior-milieu parts of a behavior setting, the synomorphs, have a specified degree of interdependence among themselves that is greater than their interdependence with parts of other behavior settings. (1968, p. 18)

In effect, a behavior setting refers to a pattern of behavior which appears regularly under specific setting-defined circumstances. As explained by Schoggen (1989): "From this viewpoint, the environment is seen to consist of *highly structured, improbable arrangements of objects and events that coerce behavior in accordance with their own dynamic patterning*" (p. 4).

Such patterns of behavior appear regularly and predictably; their occurrence is independent of the specific individuals present. These patterns of behavior are linked both in place (i.e., are circumjacent) and form (i.e., are synomorphic) to characteristics of the setting but *not* to the presence of specific individuals as much as to the presence of categories (e.g., students and teachers; players and coaches) of individuals. Within a behavior setting, the behavior and setting are "interdependent" to the extent that the former is unlikely to occur outside of the latter and that qualitative aspects of the behavior are shaped by characteristics of the setting.

Examples of behavior settings include the fit between the organization and structure of a classroom and the behaviors expected of, and displayed by, students and teachers; the distinct activities of students within a gym, in a library, or on a playground's basketball court or hopscotch grid. The physical setting and its associated rules make some behaviors highly likely and other behaviors highly unlikely. Schoggen (1989) explains that neither the physical nor social aspects of settings preclude all but a single behavior; rather, these settings aspects make "actions of some kinds easier than others" (p. 43). Wicker (1979) explains this process as follows:

> *Behavior settings are self-regulating, active systems.* They impose their program of activities on the persons and objects within them. Essential persons and materials are drawn into settings, and disruptive components are modified or ejected. It's as if behavior settings were living systems intent on remaining alive and healthy, even at the expense of their individual components. . . .
>
> . . . to summarize some of the essential features of behavior settings. Most of them can be presented in a single sentence: *A behavior setting is a bounded, self-regulated and ordered system composed of replaceable human and nonhuman components that interact in a synchronized fashion to carry out an ordered sequence of events called the setting program.* (p. 12)

Although the heuristic potential of Barker's work on setting characteristics has yet to be aggressively mined (readers are encouraged to review Levine & Perkins, 1987; Moos & Insel, 1974; and Wandersman & Hess, 1985 for illustrations of the potential richness of this vein), Barker and other environmental psychologists offer a heuristic avenue for understanding and responding to external contributors to health and pathology. That the concept of behavior settings may help unravel interpersonal processes within educational settings is strongly suggested in findings reported by Barker and his colleagues (e.g., Barker, 1968; Barker & Gump, 1964; Barker & Schoggen, 1973; Barker & Wright, 1951; Schoggen, 1989). Extrapolating from that work, it seems reasonable to assume that aspects of the environments in which people live, learn, play, and work can be shaped such that they can contribute to optimal adjustment to developmental demands and reduced potential for emotional and behavioral dysfunction.

6.13.7 TRANSACTIONAL MODELS OF BEHAVIOR

In his biopsychosocial theory of behavior, Bronfenbrenner (1977, 1979) focused attention on the synergistic relationship between the individual (e.g., IQ, temperament) and setting (e.g., parental responsiveness) in the processes of human development. Extending that theory, Sameroff (Sameroff & Chandler, 1975; Sameroff & Fiese, 1989) proposed a transactional-ecological model for understanding variation in the outcomes associated with presumably established risk factors for developmental disabilities. Unique to this model is a hypothesized "transaction" between individual and contextual factors. For Sameroff, emotional and behavioral development is the product of an ongoing synergistic series of: (i) responses by an individual to situational circumstances and demands; (ii) alterations of those situational circumstances and demands as a function of the individual's responses; and (iii) responses by an individual to that altered situation. Individual and setting characteristics, however, differ in their malleability and range of variation. Consequently, it should not be assumed that each transaction represents equivalent changes in individual and setting characteristics.

Nevertheless, within Sameroff's model, individuals and settings evolve continually (albeit generally gradually rather than dramatically) over time. This element of the theory augments substantially the complexity of understanding and controlling behavioral development. It also suggests that behavior can be shaped through controlled changes in the individual, the context, or both. Sameroff's model mirrors the continuing occurrence and adaptation to events which characterize the ongoing flow of daily life. It also offers a basis for contextualizing variations in behavior across situations. In effect, unyielding settings would constrain behaviors within circumscribed parameters. In the most recent version of the model, Sameroff and Fiese (1989) make explicit that societal (and, presumably, subgroup) expectations have regulatory influence on definitions of behavioral roles and thereby set contextual limitations on developmental outcomes. Insofar as such expectations and setting demands are fixed, the behavioral responses of those within a setting may be more restricted than assumed or desired.

Kellam's (Kellam, Branch, Agrawal, & Ensminger, 1975) Life Course-Social Field model offers further enhancement of Lewin's and Bronfenbrenner's theories. Kellam's approach integrates elements of the biopsychosocial perspective with Erikson's (1963) recognition that development involves confronting and resolving a series of social tasks across the life span. Thus, Life Course-Social Field theory defines development in terms of movement over the life span across diverse settings (i.e., social fields), each presenting its own demands and adaptive challenges.

The success with which the unique and common tasks associated within and across social fields are resolved is assessed both by oneself and by significant others in those settings. Kellam labels the substance of assessments of one's own psychological state as "psychological well-being." Examples include one's sense of self-efficacy, anxiety, self-esteem, depression, disappointment, inadequacy, etc. By contrast,"social-adaptational status" refers to the assessments which others make of the adequacy of an individual's response to these developmental tasks across the multiple contexts (labeled "Social Fields" in Kellam's model) in which we live, play, or work, for example.

Unique to Kellam's model is his emphasis on the fact that the individuals (i.e.,"natural raters") who make such assessments vary across tasks and social fields. In that sense, social fields are *social*, that is, they involve exchanges among the players in settings who have setting-related roles and expectations. Depending on their responses, these raters influence for better or worse the individual's resolution of task demands. The salience of particular social fields and of their respective natural raters changes over time and across developmental demands. Thus, the school for example, has particular salience during childhood and adolescence but much less so during the adult years. Similarly, as peers grow in importance, the family becomes less salient during adolescence and early adulthood and more so thereafter.

6.13.7.1 Linking Inside and Outside

As noted, Levine and Perkins (1997) suggested that an important obstacle to the widespread adoption of alternative perspectives of emotional and behavioral problems (i.e., as adaptations to setting conditions rather than as reflections of endogenous psychopathology) and their resolution (e.g., indirect/consultation and preventive approaches rather than psychotherapy) was the absence of "alternate theoretical conceptualizations" (p. 60). Such an alternative is now available in the growing body of work linking internal processes and external conditions. Environmental analyses reviewed thus far (e.g., Barker, 1968) provide evidence supporting the impact of external factors on emotional and behavioral functioning. Developmental theorists such as Sameroff (e.g., Sameroff & Fiese, 1989), Kellam (e.g., Kellam et al., 1975), Bronfenbrenner (1979), and Rutter (e.g., Rutter et al., 1997) extend our understanding of the programmatic significance of this impact by clarifying the transactional processes by which external and internal events influence each other.

Acceptance of such insights is heuristically important for multiple reasons. Orford (1992) notes that "one of the consequences of complex, transactional influence is that outcome is difficult to predict" (p. 33). Rather than a limitation for intervention design and application, this consequence argues for use of indirect/consultation approaches, particularly in the pursuit of preventive goals. As explained by Sroufe (1997) and Rutter et al. (1997), conceptualizing psychopathology as a developmental phenomenon shifts the focus from the individual to the individual–environment dynamic. Particularly important is recognition of such phenomena as reflecting adaptations to environmental demands rather than as the inevitable result of individual failings, unresolved early experience, biological determinism, or other endogenous factors. Within this framework, adaptive states represent points along developmental pathways. Rather than reflecting linear and deterministic processes whose outcomes are fixed from the outset (e.g., based on inherited characteristics) or soon thereafter (e.g., based on early traumatic experiences), such pathways evolve over time branching this way and that depending on specific mixes of adaptive resources, coping demands, and as yet unknown determinants of salience at the moment (e.g., Bell, 1986).

Outcome becomes difficult to predict if one requires that knowledge of beginnings implies knowledge of endings or vice versa. By contrast, emotional and behavioral states become manageable if understood in terms of antecedent processes and likely subsequent presentations (some of which may be mutually exclusive but most of which may overlap or co-occur). Such a view of pathogenesis has multiple implications (Sroufe, 1997):

(i) adaptation and maladaptation represent evolving rather than established conditions determined by what has occurred in the past, what is currently happening and the range of options allowed by cultural, setting and individual circumstances. This temporal quality of functional states links what has been with what is and *the likelihood*, ***but not certainty*** of subsequent states. Kandell's ( ) "gateway theory" of drug involvement exemplifies this principle. Use of alcohol or tobacco, for instance, is associated with an increased probability of marijuana use just as the latter is associated with an increased probability of use of cocaine or heroin. Any individual may, however, not go beyond a particular gate; hence the discontinuity between antecedents and outcomes (Kandel, Single, & Kessler, 1976);

(ii) because many characteristics of experience and environment are shared across individuals (e.g., who live in a given neighborhood or are raised within a common culture), diverse pathways may lead to a common outcome.

General systems theorists and developmental psychologists refer to this pattern as "equifinality" (Cicchetti & Rogosh, 1996; Orford, 1992). Highly diverse economic, familial, educational and occupational antecedents, for example, have been associated with drug involvement;

(iii) similarly, although individuals may share common antecedents (e.g., poverty, being reared in a single parent household; a history of physical or sexual abuse) differences in circumstances subsequent to those antecedents give rise to a variety of outcomes (e.g., depression, alcoholism, conduct disorder). General systems theorists and developmental psychologists refer to this pattern as "multifinality" (Cicchetti & Rogosh, 1996; Orford, 1992);

(iv) by combining a, b and c, one appreciates that developmental pathways offer multiple opportunities for changing direction and hence influencing outcome. Branching off may reflect the occurrence of positive or negative events (e.g., an increase in family income, parental death or divorce), the addition of individual or circumstantial resources which enhance or reduce adaptive capacity (e.g., acquisition of interpersonal problem-solving skills or access to a caring teacher) or a change in the environment (e.g., moving to a more or less violent neighborhood). Whatever the case, a seemingly normative or pathogenic process may be interrupted and its direction changed for good or ill;

(v) recognition that developmental trajectories can be altered must be tempered with appreciation of the limitations of that assertion. It appears that the further along a path one has gone and the longer the pathogenic process has been underway, the less likely it is that the path's direction can be altered. This seems to be the case because the capacity to recognize, access and use additional resources in the environment to adapt to health compromising situations depend on prior experiences, verbal abilities, interpersonal skills etc. In effect, the further along a path one has traveled, the more likely one is to reach its end point. "More likely," however, refers to probability rather than inevitability!

The conceptual option presented links exogenous and endogenous processes in a way that enriches comprehension of etiological processes and expands the avenues for interventions to influence those processes. Developmentally, emotional and behavioral patterns reflect adaptations to situational demands based on individual and environmental resources and the adaptive history of both the individual and the setting. (Mal)adaptation may proceed linearly or circuitously, winding like a river or branching out like the roots of a tree. Depending on the resistance encountered as well as what has come before, one among many alternative paths will be followed. Understanding that path will likely require understanding the history of the resistance encountered. Some of it may reflect the prior experiences of a specific individual; some may instead represent a community's, a neighborhood's, or a family's *post-hoc* response to the behavior or needs of others. Some paths will proceed in a relatively linear fashion; antecedents are followed by clinically defined emotional or behavioral problems. Removing, neutralizing, or interrupting antecedents prevents the undesired outcome.

Unfortunately, few mental health conditions can be linearly modeled. More typical is Sroufe's (1997) portrayal of emotional and behavioral development as the branches of a tree or the meanderings of its roots. Within this perspective, growth and survival requires maximizing one's access to necessary resources regardless of the impediments encountered in the environment. At any point in time, emotional and behavioral status reflects the cumulative effects of its antecedents. The further back one traces a branch the more completely one can understand what has been and will be encountered. With such information, the better one can predict the **probability** of the branch's likely direction. Where the branch connects to the trunk is but one element to be considered in predicting its various termini. That beginning is likely to be common across many outcomes (i.e., the principle of multifinality). Equally likely is that termini in close proximity may have begun at different points along the trunk (i.e., the principle of equifinality). Adding to the complexity is that some branches will end close to where they began, whereas others continue on toward other terminating points. Presumed antecedents (e.g., alcohol or tobacco use) for some conditions (e.g., substance dependence or addiction) may, for many, represent an endpoint (i.e., substance use is limited, controlled, or even ended). In other cases, however, the process continues toward dependence and addiction.

Common antecedents leading to diverse outcomes; diverse antecedents leading to common outcomes; the co-occurrence of multiple outcomes—may be perceived as too complex and misunderstood an etiological model to inform intervention design, especially preventive interventions (Lamb & Zusman, 1981). Presumably, one should wait until the die is cast, the nature of the pathology is clear, and treatment can be selected and applied. Public health practitioners might accept this approach were the costs of delay (health related and financial) minimal, the effectiveness of treatment certain, and the secondary consequences of the disorder acceptable. The common cold and the 24 hour flu fit within these parameters.

Most emotional and behavioral disorders, however, do not.

Alternatively, the aforementioned complexity may be recognized as allowing for, indeed requiring, nonspecific interventions focusing on common etiological factors, be they individual, environmental, or transactional. Targeting common risks factors or pathways which are epidemiologically linked with undesirable outcomes has the potential for impacting **simultaneously** multiple outcomes. Simply stated, interventions targeting common antecedents may impact on multiple pathways and thereby serve as a stone which kills (or at least weakens) multiple birds! By aggregating the measured preventive effects across those outcomes sharing common risks, the true impact of such interventions may finally be documented (Lorion et al., 1989). Applying the principle of multifinality to intervention design leads to targeting a limited number of shared risk factors and assessing their impact across alternative pathogenic expressions. Similarly, the principle of equifinality requires that interventions intended to reduce the occurrence of a specific outcome must target the various pathways and risks associated with that outcome. In both instances, basic elements of developmental theory supported by epidemiological findings argue against the likelihood of documenting substantial evidence of preventive outcomes if only a limited number of risks factors are targeted with the intent of impacting a single form of disorder or dysfunction. As noted below, neither prevention theory nor the traditional intervention taxonomy made that point clearly.

6.13.8 SHIFTING TO A PREVENTION FOCUS

Initial forays by the mental health sciences and professions into preventive efforts were led by Caplan (1964) who recognized that the mental health disciplines had to move beyond sole reliance on treatment if they were to serve public needs. To organize initial efforts in this direction, Caplan urged mental health to adopt the goals of and the classification system for prevention extant in public health at the time (Commission on Chronic Illness, 1957). This system was centered around the epidemiological concept of "caseness," that is, confirmation that the diagnostic criteria defining a syndrome were met. Intervention categories were differentiated within this system in terms of their proximity to the targeted condition's fulfillment of diagnostic criteria, that is, meeting the symptomatic definition of a syndrome. Preventive interventions were designed to reduce the prevalence of a targeted disease or disorder.

Within this framework, **primary** prevention interventions are implemented prior to caseness. Successful interventions reduce prevalence (i.e., overall presence of cases of a target disorder in the population) by reducing incidence (i.e., the occurrence of new cases). Potential recipients of such interventions range from the population at large, to asymptomatic subgroups targeted on the basis of epidemiologically-defined risk, to subgroups presenting prodromal signs antecedent to diagnostic status. By contrast, **secondary** interventions seek to lower prevalence by reducing the duration of caseness, that is, through the application of effective treatment. Combinations of sensitive screening procedures which identify cases early and involve them in treatment exemplify this category. Secondary approaches seek both a return to premorbid status and avoidance of subsequent episodes. Finally, **tertiary** interventions reduce the long-term disabilities and sequella consequent to caseness. Rehabilitation strategies and support services exemplify tertiary approaches. Insofar as they enable a person with schizophrenia to live independently, tertiary goals are achieved. If recurrence of disabling symptoms is avoided, secondary goals are achieved.

Ideally, primary prevention interventions are preferable. This assumes, of course, the availability of necessary etiological information, access to the population at risk, and effective intervention strategies. It also assumes that the intervention's effects are, at worse, neutral. This is a particularly important point given that the diseases and disorders of most interest to mental health are relatively low-frequency events. Hence, unless substantial risk information is available and targeting is very precise, it is most likely that the majority of those receiving the intervention are unlikely to manifest the disease or disorder in the absence of the intervention. If the intervention has iatrogenic consequences, then these individuals may be at greater risk for those consequences than to the etiological outcome to be avoided. Dismissal of this concern notwithstanding (Albee, 1986), evidence for caution has been reported (e.g., Lorion, 1987; Sameroff & Fiese, 1989) although the frequency of negative consequences appears to be low (Durlak & Wells, 1997). Secondary and tertiary prevention efforts, by contrast, are targeted only to those meeting diagnostic criteria and hence having confirmed need for the intervention.

As noted earlier (Lorion, 1983), the classic public health triad of approaches applied to the disorders (e.g., infectious diseases) and etiological processes of primary concern to public health practitioners. The applicability of its underlying causal assumptions, however, to emotional and behavioral disorders has been challenged from the outset (e.g., Albee, 1982; Lamb & Zusman, 1979). As reflected in the work of Brofenbrenner (1979), Rutter (1989), and Sameroff and Fiese (1989), there is an emerging appreciation of the etiological complexity of emotional and behavioral problems involving biological, psychological, social, and environmental parameters. This complexity obscures determination of the onset of pathogenic processes, the presence of disorder, and thereby designation of "caseness" (Lorion et al., 1989). Unresolved, these challenges produce disagreements in the categorization of primary and secondary interventions and obstacles to empirical verification of their efficacy. In either case, they allow little room for consideration of the principles of equifinality and multifinality in intervention design or evaluation.

Gordon (1983, 1987) has proposed an alternative taxonomy for organizing preventive efforts which allows for consideration of these most important developmental principles. Given the low base rate at which emotional and behavioral disorders occur in the general population, Gordon's system also allows for consideration of both the financial costs and the iatrogenic potential of the interventions. Weighting expected intervention risks with target selection, Gordon (1983) proposed that "universal," "selective," and "indicated" interventions should be designed for and targeted to "persons not motivated by current suffering" (p. 108) and neither currently seeking nor in need of treatment. **Universal** interventions are applied to the population at large and combine low costs per contact with limited likelihood of iatrogenic consequences. Examples of such approaches include public service announcements advocating seat-belt use and physical exercise or discouraging tobacco use and the consumption of alcohol during pregnancy. In the mental health realm, universal interventions include the "Friends can be good medicine" program implemented in California to enhance use of social support resources and emerging strategies to teach parenting skills to adolescents. Perhaps the designator "universal" may also be applied to the generic nature of the risk factors targeted by such interventions. If so, the difficulty of measuring their impacts becomes understandable given the multiplicity of outcomes which may be affected at undefined points in the future.

Selective interventions are targeted to segments of the population for which there is an epidemiologically established risk. Selection may be based on identified links between gender, ethnicity, economic status, or family history, for example, and the presence of emotional or behavioral disorders. Targeted subgroups have a higher likelihood of disorder and hence a more focused (and potentially more iatrogenic) intervention can be justified. Examples include programs targeted to families considering marital separation or divorce (Wolchik et al., 1993) or the recently widowed (Silverman, 1988).

Indicated interventions target individuals (rather than subgroups) who present risk factors or prodromal signs indicating substantial individual risk for subsequent disorder. Examples of these approaches include programs for women presenting early indices of depression (e.g., Vega, Valle, Kolody, & Hough, 1987) and adolescents referred to juvenile court for status offenses (Lochman, 1992). It also includes Olds' substantially validated approach to assisting high-risk adolescent mothers (Olds & Korfmacher, 1997, 1998a, 1998b).

Gordon's proposal was intended to stimulate development of preventive efforts and to make explicit how they were clearly distinct from treatment of symptoms and syndromes. In an important sense, Gordon (1983) proposal offers a conceptual expansion of the original "Primary prevention" category. His approach highlights the breadth of opportunity available to influence prevalence by intervening along that functional continuum ranging from health through various prodromal stages prior to meeting diagnostic criteria. The richness of this alternative system lies in its clarification of concepts of "risk" and "vulnerability" as applied to individuals, situations, and their combinations. It also lies in its clear distinction between the end-state conditions to be avoided (e.g., substance abuse or depression) and susceptible individuals. Sameroff (1977) made a similar plea in his early warning to prevention scientists that their efforts must not compromise respect for the humanity of the recipients of those efforts. In his advocacy for health promotion efforts, Cowen (1996) similarly urged program developers to recognize that removal or reduction of risks and vulnerabilities could leave individuals both empowered and likely to reach their potential. In their meta-analytic study of primary prevention programs, Durlak and Wells (1997) report clear evidence of the value of skill-building and competency enhancement as a means of avoiding dysfunction as well as improving quality of life for at-risk youth.

6.13.9 MERGING INDIRECT/ CONSULTATION STRATEGIES WITH PREVENTION GOALS

Whatever classificatory scheme is adopted, epidemiology and developmental psychopathology provide important conceptual and methodological foundations for meaningful advances in prevention (Mrazek & Haggerty, 1994). Application of case–control methodology, for example, enables epidemiologists to discern potential risk and protective factors associated with symptomatic and syndromal expression. Developmental psychopathology's longitudinal methods offer insights into the pathogenic processes defining vulnerability and allow for modeling the sequence of states and events which define the trajectory from health to dysfunction, to distress, and potentially (but not necessarily) to pathology. As noted, examination of developmental processes from a system's perspective brings to the forefront the importance of the principles of equifinality and multifinality. In turn, the application of these principles argue for the design and implementation of preventive interventions which target multiple risk factors linked to one or more negative emotional and behavioral outcomes. This view is supported by Mrazek and Hall (1997) who question Durlak and Well's (1997) decision to exclude programs which sought to improve academic achievement and reduce substance use from their meta-analysis of preventive interventions:

> Even though this is a legitimate way to narrow the huge task they faced, it also represents one of the main problems in prevention science today, that is, the categorical approach to mental, social, educational, behavioral and legal problems. Many of these problems have common risk factors that interact in complex causal chains. Addressing clusters of risk and protective factors increases the chances of preventing multiple problems in many areas of functioning. It is the accumulation of multiple proximal outcomes across various domains of functioning, such as educational status, social adjustment, and behavioral and emotional well-being that will be the most convincing arguments for the effectiveness of prevention. (Mrazek & Hall, 1997, p. 223)

Impacting on such a diversity of targets requires in my view the application of indirect and consultation strategies to maximize achievement of desired outcomes. As noted earlier in this chapter, such approaches characterized early twentieth century attempts to respond to the needs of children and families at risk for emotional and behavioral problems. Across multiple settings and a diversity of goals relating to improving the status of those in need, such early efforts at consultation applied expertise in developmental processes and mental health to enhancing the effectiveness with which parents, teachers, and other members of a community met their responsibilities. Consultants observed behavior, examined policies, and procedures, identified and examined the assumptive bases of definitions of problems and solutions, and thereby opened new perspectives and alternatives to those whom they served. The recipients of their services, in turn, impacted on the lives of the children and families deemed to be at risk.

Reviews of mental health consultation (e.g., Bloom, 1984; Gallessich, 1986; Mannino & Shore, 1986) reveal both the promise and limitations of attempts to extend these early efforts to meeting the mandates of the Community Mental Health Centers Act. Whether focused on the needs of a client being provided mental health services, of the provider delivering those services or of the agency in which those services, were delivered, consultation was generally targeted to responding to the needs of those with identified dysfunction or incipient forms of disorder. The delivery system itself was not altered nor were the conditions for providing its services.

What seems necessary at this time is the application of indirect/consultation strategies which redefine service delivery systems and thereby impact on the common risk factors seemingly essential to the etiology of diverse emotional and behavioral problems. Durlak and Wells' (1997) meta-analysis of prevention programs for children and adolescents makes evident the promise of such interventions. Similar optimism is supported by the findings of the recent Institute of Medicine review of the state of preventive science (Mrazek & Haggerty, 1994). What both reviews underline is the importance of focusing on building skills in the individual at risk or in those who surround the individual. Preventive interventions with the most promise appear to strengthen basic academic skills, interpersonal resources, and the responsiveness of the social systems which can influence developmental outcomes (Durlak & Wells, 1997; Lorion, 1990; Mrazek & Haggerty, 1994). The best of such work is theory-based, systematic and, most importantly, **incremental** (Price, 1997; Price & Lorion, 1989). Like the pieces of a puzzle whose image gradually emerges, program development proceeds through the sequence depicted by Price (1983) as the "four domains of prevention science" (p. 291). These domains include: (i) problem analysis (i.e., epidemiological and etiological studies); (ii) innovation design (i.e., program development); (iii) field trial (i.e., efficacy research); and (iv) innovation diffusion (i.e., effectiveness research).

A most important element of Price's model for the development of preventive intervention was the interconnectedness of these domains. In effect, Price recognized how progress through these stages modifies one's initial understanding of the originating problem and hence catalyzes the refinement of each subsequent stage. Earlier, Cowen (1980) had differentiated the initial two domains as "generative" and the latter two as "executive" components of prevention science. Generative studies have scientific importance beyond their capacity to inform the design and implementation of interventions for they inform us "about the very processes whereby functional and dysfunctional states develop and are maintained. Preventive research can increase our understanding of the environmental parameters which engender, maintain, and modify human behavior" (Lorion, 1983, p. 264). The continuing heuristic value of Cowen's distinction between generative and executive studies and Price's four domains is reflected in the Institute of Medicine's analysis of the state of prevention science. To catalyze the field, the report advocates that the field adopt the "preventive intervention research cycle" as its map for the systematic accumulation of information (Mrazek & Haggerty, 1994). Optimistically, they conclude:

> If the research standards and methodology outlined here are systematically and rigorously applied within the preventive intervention research cycle and the guidelines on cultural, ethical, and economic issues are carefully considered at each step, prevention research will yield progressively more powerful results over the next decade. The ensuing development of prevention into a science will provide a firm base of knowledge for policymakers. This knowledge will inform their decisions on the allocation of available resources toward the ultimate goal of realizing the opportunities presented by the science for the alleviation of the personal and societal suffering and burdens associated with mental disorders. (pp. 408–409)

The validity of this assertion is clearly represented by the Home Visitation Program developed by Olds and colleagues and described in detail in two special issues of the *Journal of Community Psychology* (Olds & Korfmacher, 1997, 1998a, 1998b). Built slowly and methodically over more than two decades, this program exemplifies the challenges and potential payoffs of the systematic pursuit of preventive goals. Of direct relevance to this chapter is that the program relies on a mixture of direct and indirect intervention components to accomplish its goals. These components derive from recognizing the complementary aspects of self-efficacy, human attachment, and human ecology theory. Recipients of the program's direct intervention are primiparous (< 26 weeks gestation), young (< 19 years of age) women who are deemed at risk because they are single and/or low-income. Program goals for these women included the reduction of pre- and perinatal risks to decrease epidemiologically established risks for health problems in late pregnancy, delivery complications, and associated developmental sequella for the infant. The program also sought to alter parenting practices associated with negative child health and developmental outcomes. Finally, the program sought to improve maternal life course by extending the interval between the initial and subsequent pregnancies and thereby increase the likelihood of mothers returning to school, obtaining work, and becoming independent of welfare. Women were randomly assigned to intervention or control conditions and the intervention was provided initially by registered nurses (a comparison of the differential effectiveness of nurses and paraprofessionals is currently underway).

The program began in Elmira, NY with a predominantly White, rural sample and was replicated and extended with an urban, African-American sample in Memphis, TN and a diverse sample in Denver, CO. The initial cohorts have now been followed for nearly two decades. In considering the findings, the complexity of this program becomes evident. Through contacts with the home visitor during the final stages of the pregnancy, mother's knowledge, attitudes, and behaviors concerning health compromising risks (e.g., diet, exercise, alcohol, and tobacco use) are to be influenced with the hope of reducing birth complications and optimizing fetal development. Following the birth, home visitation continues its focus on maternal health as well as child care, developmental processes, and, importantly, the implications of maternal choices on the life course. The latter is important insofar as the mother assumes control of the timing of subsequent pregnancies as she recognizes its implications for her educational and employment options and their implications for her immediate and long-term economic situation.

From this perspective, the program delivers a direct service to the mother. The lack of a mental health diagnosis notwithstanding, the service appears similar to many forms of treatment. The visitor meets regularly with mother to discuss issues, provide information, and offer counsel and support. The notable difference, however, is that at least a portion of the changes in the mother are intended to alter permanently **her** behavior toward her child. Not unlike the Child Guidance and Settlement House social programs of the early twentieth century, the Home Visitation program represents a form of indirect/consultation service. Toward this goal, the program strategy is designed to enhance the mother's capacity to parent and to assert herself in employment and social service situations. If this element of the program is successful, significant risks for the child (e.g., developmental lags, physical or sexual abuse, early academic failure) can be reduced which have been linked epidemiologically to school failure, conduct disorder, substance involvement and, later in life, early pregnancy, and cross-generational child abuse.

Changes in a mother participating in the Home Visitation program, therefore, can ripple across the family, home, neighborhood, and other levels. Assuming that the program's effects on the mother are lasting, developmental benefits observed in the developmental course for the firstborn should hold for subsequent children as well. To the extent that mother's overall heath behaviors and especially prenatal health behaviors are improved, further reductions in neonatal risk should occur for subsequent children. If the intervention represents a viable approach to assist women to move from welfare to employment, program effects support the achievement of indirect/consultative goals at the public policy level.
